THE TREATMENT OF PULMONARY TUBERCULOSIS.¹

By JOSEPH O. HIRSCHFELDER, M.D.,

OF SAN FRANCISCO, CAL.;

PROFESSOR OF CLINICAL MEDICINE IN THE COOPER MEDICAL COLLEGE.

IN the November number of the *Occidental Medical Times* of last year I described a method of treatment of pulmonary tuberculosis which was based upon some original conceptions of the mode of generation of antitoxins in the animal body. Further research and clinical experience has enabled me to confirm the statements made at that time, and also those contained in an additional note published one month later. My clinical observations, and those of my colleagues who have investigated the remedy, have established the efficacy of oxytuberculin beyond a doubt. Culture experiments, as will be seen, show how the agent acts and enables us to measure the potency of each preparation of the oxytuberculin in a manner that has not yet been possible with any of the antitoxic serums.

Before the year 1890 the attitude of the medical profession toward pulmonary tuberculosis was that of almost absolute helplessness. We had learned to diagnosticate the disease in its early stages by the microscopic examination of the sputum through the presence of the bacillus tuberculosis, but we felt that when we had established the presence of the dread disease all that we could do was to send the hapless patient to a congenial climate in the hope that fresh air and exercise might prove of benefit. As far as active therapeutic intervention was concerned, however, we knew that we could do nothing. Then came the glad tidings that Koch had found the long-sought-for specific—that his tuberculin was the certain cure for tuberculosis wherever it might be found. We shall probably never again witness such enthusiasm in medical circles as that which was aroused by Koch's demonstration. We had learned to look upon his statements as demonstrated facts, for he had never until then enunciated a doctrine which had not been found to be correct. We even felt that the secrecy of the remedy was to be forgiven in him—although in another such a procedure would have been considered quackish. Truly it seemed marvel-

ous that an infinitesimal quantity of an organic liquid injected under the skin of a tuberculous individual should cause a violent febrile reaction with congestion of the tuberculous mass, and no effect on other tissues. Everyone was eager to try the new remedy even if he did not know what it was, and happy was he if he were one of the favored few who could obtain it at any price. But the reaction came only too soon. Virchow showed at the *post-mortem* table what the influence of the tuberculin really was. In a large number of cases death was hastened by its use and dissemination of tubercle was induced by it to an extent that the great pathologist had not seen before. From that time on the credit of tuberculin began to wane, and soon it fell into disrepute as a remedy for tuberculosis with the vast majority of physicians. It still holds its place for diagnostic purposes, for the febrile reaction following its injection is a certain sign that tuberculosis is somewhere present in the body. We now know what tuberculin is and how it is prepared. Upon the surface of veal bouillon containing glycerin and peptone a pure culture of the bacillus tuberculosis is floated and cultivated at 38° Centigrade. After six to eight weeks a pellicle will have covered the surface and sunk to the bottom of the vessel. The fluid is then sterilized by heat, filtered through a Pasteur filter and evaporated to one-tenth its volume. This is the crude tuberculin such as was formerly used. Now this crude liquid is precipitated with alcohol, washed, and dissolved in water.

Feeling that there was an element of truth in the statements of Koch that tuberculin cures consumption, and that the ill effects resulting from its use must be due to some extraneous foreign elements, several investigators have attempted to purify it and have used what they supposed to be a purified tuberculin under various names. The most prominent of these preparations is that of Klebs, which he terms "antiphthisin." Unfortunately the claims made by Klebs have not been confirmed by experience. Trudeau has clearly proved that antiphthisin is merely a very dilute tuberculin. We will see during the course of these remarks that Trudeau was quite correct when he stated that Klebs erred in affirming that tuberculin inhibited the growth of the tuberculosis bacillus, for he showed that it is the acid that develops in the culture-fluid which acts as a preventive of further growth. I can confirm Trudeau's state-

¹ Read before the California State Medical Society.

ments, for in equal parts of tuberculin and veal bouillon which has been made alkaline, the tubercle bacillus grows as freely as in the plain veal bouillon. Clinical observations have been as adverse to the claims of Klebs as have been laboratory experiments.

In 1890 Behring enunciated the doctrine of the antitoxic substances which develop in the animal organism from the bacterial toxins, and this led to the introduction of the antitoxin of diphtheria into general medical practice. In spite of occasional adverse criticism and an occasional death due directly to the remedy, it has proved its value in the treatment of diphtheria beyond a doubt, and thousands of lives are yearly saved that would otherwise undoubtedly have been lost.

Stimulated by these excellent results, numerous investigators have attacked tuberculosis in a similar manner and have probably met with some success. This is true of Paquin in our country and Maragliano in Italy. Their method of procedure is to inject gradually increasing quantities of tuberculin hypodermically into a horse until the animal becomes immune to such large injections. The blood is then drawn from the jugular vein into a sterile flask, allowed to coagulate in a cool place, and the sterile serum is drawn off for use as the antitoxin. It will require a long observation of results by many clinicians before we will be able to arrive at a knowledge of just how much may be accomplished by this serum. But even if it should be finally proved that an antituberculin develops in animals so treated, its use as a curative agent in man is attended by several obstacles and dangers. In the first place, the quantity of tuberculin used, and hence the quantity of antituberculin developed, is so infinitesimal that when dissolved in the blood and plasma of the animal it is present in such minute proportions that the numeral would be far removed from the decimal point in its representation in figures. In the second place, the antituberculin elaborated in the blood must be administered dissolved in the serum of the animal. We know from several deaths which have immediately followed the administration of the diphtheria antitoxin that this is by no means an indifferent substance which may be administered in unlimited quantities. We know that in the animal body the antitoxin develops in some manner from the toxin; if we were able to discover the process it is clear that we might be able in our laboratories to imitate the method and so produce the sought-for remedy in unlimited quantities and free from deleterious admixture. Until now no satisfactory theory has been established, and no indication has been given of the lines upon which to proceed.

With regard to tuberculosis, however, it seems to

me that the course to pursue has long been before the medical profession even though we have been unable to read what Nature has written for us in her hieroglyphics. The theory which lies at the foundation of the therapeutic measures about to be described is even more important than the results themselves, for if it should be found to be correct, it will be an addition to our biologic knowledge of the greatest scientific importance. This theory was thought out early in October, 1895, and the various modes by which it might practically be applied were clear before a single step was taken. In other words, the theory was not evolved from the therapeutic results, but the method of treatment was a consequence of the biologic proposition. The therapeutic success may therefore be looked upon as a verified prediction, and hence has far greater evidential value than it otherwise could have. The treatment of patients by the new method was very cautiously begun on October 22, 1895, and as the results warranted, the doses were gradually increased until after a few months efficient quantities were administered. I am pleased to be able to say that to my knowledge no patient has been injured by the use of the remedy.

In 1864 Spencer Wells performed laparotomy, in consequence of an erroneous diagnosis, upon a patient suffering from tuberculous peritonitis. Contrary to all expectations, the patient recovered. Numerous cases have since been reported in which the same favorable results occurred; indeed, the peritoneum which was observed at the operation to be studded with tubercles has been found years after, at a second operation, to be smooth and free from all tuberculous deposits. Distant tuberculosis has also been observed to disappear after laparotomy upon a tuberculous peritoneum. It appears most probable that in these cases the entrance of air into the peritoneal cavity must have been the important factor; that an oxidation of the tuberculin present in the effusion was thus brought about and that it was this oxytuberculin which effected the cure both of the local and of the general tuberculosis. It certainly seems a very probable hypothesis that it is by oxidation that the toxin is changed into antitoxin in the animal body, for there is no process of the economy so universal as oxidation. The first and most evident result of the introduction of a toxin is fever, with increased oxidation as if Nature was striving with all her power to change by this process the poisonous substance into its antidote.

Acting upon this hypothesis the problem of finding a method of oxidizing the toxin without completely destroying it presented itself, and various methods of accomplishing this result were investigated. I will not weary you with a description of the different forms

of experiment which were attempted, nor of the steps which were taken until the method was finally perfected, but shall describe in as detailed a manner as I can the mode in which oxytuberculin is now manufactured. I found very soon in the course of my experiments that the peroxid of hydrogen was the substance for which I was seeking, and that it is a powerful oxidizer but not so destructive as is generally supposed. When I added it to tuberculin at a low temperature and injected the latter into a tuberculous patient or animal even after the mixture had stood for some time it produced the same reaction as if pure tuberculin had been used. I found that in order to avoid such reaction it was necessary to heat the mixture for at least ninety-six hours. I have lately found it wise to lengthen the period of heating even more, and now I sterilize it for 120 hours, obtaining better results than formerly. I formerly used the tuberculin prepared by Koch in Berlin, but have been able to obtain still better results with one of my own growth, made by the development of a highly virulent bacillus of tuberculosis upon veal bouillon containing four per cent. of glycerin, one per cent. of peptone, and one-half per cent. of chlorid of sodium, to every liter of which, when neutralized, 3 c.c. of a normal solution of carbonate of sodium is added. In this culture-fluid the germ has developed with gradually increasing rapidity so that whereas ordinarily it takes six weeks for the culture-fluid to be completely covered by the growth, this now occurs in my laboratory in less than three weeks. Injected into guinea-pigs it kills many of them in less than three weeks, the organs being overwhelmed with tuberculous nodules.

After the germ has fully grown so that the tuberculous scum which floats on the surface begins to sink, the flask is sterilized by heat for two hours, and the contents are filtered. This is the tuberculin I use. A measured quantity is put into a stone jug and one-tenth the quantity of a ten-volume solution of peroxid of hydrogen is added, and the jug is stoppered with cotton and put into a sterilizer at 100° C. Every twelve hours the same quantity of peroxid of hydrogen is added until the process has been repeated the tenth time, so that, in all, the quantity of solution of peroxid of hydrogen added shall equal the quantity of tuberculin used. This is then heated to 100° C. for twelve hours longer, and at the end of that time (120 hours in all) it is found still to contain free peroxid of hydrogen, is highly acid, and is decidedly darker than was the original tuberculin. It is made alkaline with caustic soda and reheated to drive off the excess of peroxid of hydrogen. Five per cent. of boric acid is added to keep it from decomposing. It is filtered into sterile vessels and is ready for use.

It now does not contain a trace of the peroxid of hydrogen, which has all been changed to water.

Theoretical objections have been made to the process by some who claim that the peroxid of hydrogen must rapidly be destroyed by the organic substances present in the liquid. It is very easy to prove that this supposition is incorrect, for at any stage of the process up to the final addition of the alkali free peroxid of hydrogen may be found by the usual chemical tests, such as the blue color which develops with the iodid of starch, and the pretty reaction with a mixture of bichromate of potash and sulphuric acid, in which the free peroxid of hydrogen causes a beautiful blue color to develop.

The greatest possible care is necessary in the preparation of this oxytuberculin, for if any appreciable quantity should escape oxidation fatal tuberculin poisoning might result from the large quantities which must be administered. It should be carefully tested, first on animals and then on patients. This oxytuberculin, after it has been thus carefully prepared and tested, is injected hypodermically into any part of the body. I prefer the back and inject the remedy well under the skin. The most scrupulous care must be taken. If the lymph should be in the least clouded, or any other condition be present that would suggest infection, it should be sterilized by heat for at least fifteen minutes. Ordinary syringes should not be used, but such as are employed with antitoxin. I have made many thousand such injections without causing the formation of a single abscess or even an induration of the skin. The liquid causes no greater local disturbance than any indifferent fluid would produce. There is no reddening of the skin or other sign of localized inflammation. In a few minutes the fluid injected is absorbed and the patient suffers no further inconvenience except sometimes a little smarting at the site of injection. There is no rise of temperature, or any other unpleasant constitutional effect. Within a few days the cough and expectoration diminish, and the most striking effect is the rapid improvement in the appearance of the patient. His eyes become bright and his color changes from the gray hue of tuberculosis to one more nearly resembling that of health. The appetite rapidly returns, and with it a feeling of vigor which is most pleasing to the patient and to the physician. This is especially evident in the very early cases in which there is little or no fever. In cases in which only slight fever is present the higher temperature soon diminishes and in many instances becomes entirely normal. At the same time the infiltration of the lung gradually disappears, so that a most careful examination fails to reveal any deviation whatsoever from the normal after the treatment is completed.

The tubercle bacilli in the sputum may rapidly diminish in number and finally disappear altogether, as I have found in a number of cases.

Every physician has seen patients with tuberculosis recover, but it has never before been my good fortune to witness such rapid changes as have taken place in several that had been examined by other physicians both before and during the treatment. The patients that have recovered have thus far remained well. If any test of the method should be made by other members of the profession I would earnestly request that provisionally only early cases of the disease be treated, in which there is no development of cavities in the lung, in which fever is slight, and in patients in whom the constitutional condition is such that a return to health may reasonably be expected.

One of the most striking demonstrations of the value of the remedy occurred in a case of tuberculosis of the hand. A physician infected the dorsum of his right hand, and an ulceration developed which microscopic examination showed to be tuberculous. It was treated in the usual manner, and without beneficial result, so that the surgeon was about to make an extensive excision which was to be followed by skin grafting. Instead, local applications of the oxytuberculin were made and very rapid healing took place, leaving behind the same kind of scar as would have resulted from a non-infected ulcer. As a confirmation of this observation I show you here a dog that was vaccinated upon the back in a large number of places with a virulent pure culture of tubercle bacilli. After a short time, numerous tuberculous ulcers developed, in the pus of which the bacilli of tuberculosis were demonstrated. A section made by Dr. Rixford showed bacilli in the tissues. The dog was then chloroformed and a piece of the skin with the tuberculous ulcers was removed. The dog was then treated daily with hypodermic injections of oxytuberculin. The ulcers rapidly healed, and you now see the animal with the scar resulting from the removal of part of the tuberculous skin but with no sign of the disease with which he was inoculated. I will say that since the injections of oxytuberculin the dog that was ailing, feeble, and without desire for food, has become bright, strong, and vigorous, and has developed a voracious appetite.

The patients that have been treated by me with the oxytuberculin, those who came in the very early stage of the disease, before cavities were present, have been rapidly cured. By cure I mean a complete cessation of cough and disappearance of all symptoms of disease on the part of the patient, together with the return of a normal condition of the lung, as shown by physical examination. Above all,

do I demand in these cases that the tubercle bacilli shall no longer be found in the sputum. Patients in whom the disease was moderately advanced have likewise rapidly improved, and some have entirely recovered. Of the very advanced cases, many have shown marked improvement, and many patients that I have declined to treat as being too far advanced but who pleaded so hard for the treatment that I could not refuse, have surprised me by the wonderful improvement they have shown. Some in the last stages of the disease who presented themselves with high fever, and who were cyanotic and gasping, have died. No treatment could be expected to benefit such patients. Of course they throw a cloud upon the statistics for they must honestly be reported with the more favorable ones. I shall therefore present to you all of the cases I have treated with oxytuberculin, but request you not to judge of the treatment by the advanced cases, for which I make no claim, whatsoever.

In order to systematize our observations I will divide the cases into four sets depending upon the stage of the disease. In the first stage we find infiltration of the lungs, with more or less pallor, loss of weight, and cough, and with sputum containing tubercle bacilli. The bacilli may be absent at repeated examinations and yet finally be found. In the second stage there is extensive infiltration of the lungs, with hectic fever, emaciation, and a large quantity of sputum containing the bacilli, but no cavities. In the third stage there are cavities, but still a fair degree of vigor. There is no dyspnea when the patient is quiet, but marked shortness of breath on exertion. In the fourth stage there are large cavities, with the usual signs of advanced consumption, and the dyspnea is very decided even when the patient is sitting or lying down.

Many of the patients here presented in person and represented in the accompanying table have been seen by other physicians before and during the treatment. My colleagues have confirmed my observations, and I am certain that they will agree that I have not erred in making my reports too favorable. It has been my purpose to be as skeptical as possible and I have striven to make the showing rather less favorable than too much so. I find that the patients that had been treated with oxytuberculin insufficiently oxidized did not give the same results as those treated with the newer preparation, and therefore have tabulated the cases separately.

Clinical observation having thus shown the very marked effect of oxytuberculin, it remains for us to establish in what manner this cure is effected. There are two methods by which the body may rid itself of an invading micro-organism; the one is by the en-

feeblement of the germ, and the other is by the invigoration of the body so that it becomes sufficiently potent to expel the invader. We know that we are all constantly taking the bacillus of tuberculosis into our bodies. It has been shown by Loomis at *post-mortem* examinations of healthy individuals who have died from accident that many have tubercle bacilli stored up in the bronchial glands, out of harm's way but alive and able to infect guinea-pigs when injected into them. Again, we constantly observe that tuberculosis develops when the patient becomes physically depressed, when the vital forces are at low ebb. On the other hand, innumerable patients with consumption recover under the influence of favorable hygienic conditions. The antitoxins of the infectious diseases probably act in a somewhat similar manner, for experiment has proved that they neutralize the pernicious toxins which are formed by the germs and which enfeeble the body by their poisonous influence. Upon the germs themselves they have little influence, for we know that pathogenic organisms flourish in the very serum which is used to antagonize their effect upon the body. How is it with oxytuberculin? It will be my privilege to prove to you that oxytuberculin directly prevents the growth of the bacillus of tuberculosis; that its action is specific upon that germ and that it is not due to a general antiseptic effect. If we take veal bouillon containing 4 per cent. of glycerin, 1 per cent. of peptone, and $1\frac{1}{2}$ per cent. of salt, and add to every 1000 c.c. thereof, when neutralized to litmus, 3 c.c. of a normal solution of carbonate of soda, we will find that the bacillus tuberculosis will grow vigorously upon it. If we mix this veal bouillon with equal parts of tuberculin, made similarly alkaline, the germ will flourish just the same, but if we use oxytuberculin made from the same tuberculin rendered alkaline to the same degree, the bacillus of tuberculosis will not grow. In other words, the oxytuberculin inhibits in the culture-tube the growth of the germ of tuberculosis just as it cures the consumption in the patient. Not only can this be proved by the simple culture experiment, but the strength of the oxytuberculin can most accurately be gauged by the same process. If to our standard alkaline-glycerin-veal-bouillon we add oxytuberculin in varying proportions, it will be a simple matter to find the weakest dilution of the oxytuberculin in which the growth of the bacillus will be inhibited, and thus it may be standardized. In a similar manner any oxytuberculin may be standardized, so that when we use it we may know accurately how potent the remedy is which we are employing. Such a method of estimating the strength of a preparation is infinitely superior to that of judging it from its effect upon more or less resistant animals.

From the very beginning of the experiments it was my purpose to discover some means of knowing how long I should continue the oxidation in order that all of the tuberculin should be changed to oxytuberculin, and none of the latter be destroyed. There was no chemical test known, and all of my efforts to find one were in vain. I was therefore compelled to make use of the reaction of tuberculous guinea-pigs to find the point when no effective tuberculin could be found. It is clear that a certain amount of the tuberculin might be present but neutralized in its effects by the oxytuberculin. Under such circumstances we would get no deleterious tuberculin influence, but still not the best possible oxytuberculin action. In the manufacture of the oxytuberculin I had gradually begun to lengthen the time during which I heated the tuberculin with the peroxid of hydrogen, and finally decided upon the method of sterilizing for four days. Oxytuberculin so prepared gave excellent results and no reactions until I happened to use large doses (40 c.c.) in the case of a highly sensitive hospital patient. A slight rise of temperature occurred that made me feel that all of the tuberculin had not been converted. About this time I had discovered the inhibitory influence of the oxytuberculin, and I immediately concluded that this influence would teach me what was the best length of time to continue the oxidation. I reasoned that if my theory was a correct one, as I continued the oxidation, this inhibitory power must gradually increase until the maximum is reached, and as the oxytuberculin produced is gradually destroyed by further oxidation, from this point on there must be a gradual decline of this inhibitory power. Such, indeed, was the result obtained. I sterilized tuberculin with peroxid of hydrogen for 176 hours, adding the peroxid every twelve hours and removing portions of the lymph for comparison at 96, 120, 144, and 156 hours. The final oxytuberculin which had been sterilized 176 hours contained but fifty-three per cent. of the quantity that was present in that sterilized only ninety-six hours, and in order to make a fair comparison, after free peroxid in all the preparations was removed by rendering them alkaline and heating, all were diluted to the same proportion with distilled water, the quantity added depending upon the degree to which it had been diluted in the process of preparation by addition of peroxid of hydrogen, which, of course, had become changed to water. All of the preparations were then neutralized and three-tenths of one per cent. of normal carbonate of soda added. Each of the oxytuberculins was mixed with an equal quantity of standard veal bouillon and inoculated with a pure culture of the bacillus tuberculosis. As a control, standard veal

bouillon was mixed with an equal quantity of water to which three-tenths of one per cent. of normal carbonate of soda was added and was likewise inoculated with the same germ. There was rapid growth in the veal bouillon, less in the 96-hour oxytuberculin, and hardly any in the 120-hour oxytuberculin, which, you will remember, had been diluted with water and veal bouillon to only 26½ per cent. In the 144-hour oxytuberculin growth increased, was greater in the 156-hour preparation, and in that sterilized 176 hours was almost as great as in the veal bouillon. This simple experiment not only confirmed our previous culture-tests, but likewise taught that at least 120 hours and less than 144 hours are necessary to obtain the best results. In point of fact, as soon as I began to use oxytuberculin so prepared upon my patients immediate and striking results occurred such as I had not witnessed before. I shall now narrow the range still more by tests of oxytuberculins heated for different periods between 120 and 144 hours. I have done this in part with another sample of oxytuberculin which was sterilized 144 hours and a portion removed after 134-hours' sterilization. These were made 0.3 per cent. normal alkaline, and each was mixed with equal quantities of standard veal bouillon. They were inoculated with tuberculosis at the same time as was veal bouillon. Three cultures of veal bouillon and four each of 134- and 144-hours' oxytuberculin were made. All of the veal bouillon and all of the 144-hour oxytuberculin flasks showed vigorous growth and none of the 134-hour oxytuberculin flasks.

Provisional experiments made with cultures of staphylococcus, micrococcus ureæ, bacillus typhosus, and bacillus diphtheriæ have given results analogous to those obtained with the bacillus tuberculosis. Cultures of these germs were sterilized and filtered in the same manner and were oxidized similarly with the peroxid of hydrogen for various periods and then treated in the same manner. They were likewise mixed with veal bouillon and inoculated with the respective germs, as was a control with veal bouillon. In all of them a complete suppression of the growth of the micro-organism occurred, but the length of time that oxidation was necessary to produce this result differed with different germs. The presence of the inhibitory action of the oxytoxin upon growth of the germ in four cases, in addition to that observed, proves the universality of the law and permits us to reason from analogy that not only will all of these diseases yield to oxytoxic treatment, but that this must be true of every disease the germ of which we can cultivate.

I will now call your attention to the tables which show the effect of the oxytoxins of the various germs.

As my attention had been directed to the faint possibility that the inhibitory influence might be due to the reaction of peroxid of hydrogen on veal bouillon, I treated that liquid with the oxidizer in the same manner as the cultures, sterilizing for 130 hours, and found that it had no effect whatsoever in any case.

All of these tests show conclusively that the oxy-tuberculin inhibits the growth of the bacillus of tuberculosis. That this is a specific effect and not due to a general antiseptic action is proved by the facility with which other germs develop in the fluid. From all of the statements made, I believe that I have proved beyond reasonable doubt that consumption may be cured by the use of oxytuberculin if the remedy is administered during the early stages of the disease, and that the cure is effected by a direct action upon the causative germ.

Dr. William Thompson of Philadelphia Honored.—The Trustees of Jefferson Medical College have elected Dr. William Thompson Emeritus Professor of Ophthalmology at that institution in recognition of his services as a teacher of diseases of the eye during a period of nearly twenty-four years.

TRAUMATIC PROLAPSE OF THE IRIS AND ITS TREATMENT.¹

BY G. E. DE SCHWEINITZ, M.D.,

OF PHILADELPHIA:

PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE.

EVIDENTLY no single rule of surgical conduct is applicable to each case of traumatic prolapse of the iris, and for the sake of convenience, as well as for therapeutic consideration, these lesions may be considered from the regional standpoint, *i.e.*:

I. *Cases of Prolapse of the Iris Through Wounds at or near the Corneoscleral Junction, Forming the Well-known Pouch-like Hernia.*—If seen early, that is before the anterior chamber has been reformed, owing to closure of the wound by adhesive inflammation, three courses are open to the surgeon:

1. Replacement of the prolapsed iris and the management of the case in the ordinary manner with pressure, bandage, and rest; or, in the event of failure,

2. Abscission of the prolapsed iris, precisely as in the operation of iridectomy.

If either after replacement or abscission the wound shows a tendency to gape, or is not neatly coapted, and hence the danger of re prolapse is rendered likely, the wound may be closed with one or more delicate silk sutures.

3. Compressive bandage, rest, etc., without manipulation or abscission of the iris.

Although the advice to replace the prolapsed iris, if possible, is always given, and properly so, in point of fact the opportunities to accomplish this maneuver successfully are comparatively rare, and hence practically the choice lies between an operative and non-operative procedure.

Eyes with this lesion treated without surgical interference, and which heal without infective inflammation, present an adherent peripheral leucoma and an oval, mobile pupil, and have good vision. Sometimes, indeed frequently, healing proceeds without signs of reaction; at other times there is iritis and ciliary irritation, and withal the nuisance of prolonged bandaging and protracted convalescence.

Eyes with this lesion successfully treated by abscission, with or without a stitch, according to the indications, heal with comparatively little scar and present a narrow keyhole-shaped, mobile pupil and non-adherent iris. The time required for cure, as compared with cases treated upon conservative principles, is short. An illustrative case is the following:

CASE I.—A laborer, aged twenty-four, was struck in the right eye with a chip of wrought iron, causing a small, irregular wound, beginning directly at the

corneoscleral junction in the upper and inner quadrant, and passing irregularly inward across the ciliary region for a distance of one centimeter. When examined, nine hours after the accident, the tension was minus two. Through the wound in the corneoscleral junction protruded a mass of iris and blood-clot and the face of the iris (the anterior chamber was empty) was covered with a large blood stain. Vision amounted to counting fingers at six inches. A red reflex was visible from the eye, but the details of the fundus could not be seen. After sterilization of the conjunctival sac with repeated forced flushings with a saturated boric-acid lotion, the lips of the wound were separated and all prolapsed iris and adherent clot abscised, in precisely the same manner as when the operation of iridectomy is performed. With a flat spatula, the edges of the coloboma were carefully smoothed and the incision in the sclera neatly coapted. A drop of atropin was instilled, a light, sterile bandage applied, and the patient put to bed with the following directions to the nurse: One-sixth of a grain of calomel every two hours; continuous iced compresses to the injured eye, these compresses being placed upon the folds of the gauze bandage; and rest as much as possible in the dorsal position. In forty-eight hours the wound was closed and the anterior chamber restored. At the end of ten days the patient was dismissed with a neat coloboma upward and inward, a healed corneal wound, an iris of normal color, the media clear, and vision $\frac{20}{40}$ without correcting lens. With correction of the acquired astigmatism, which will lessen, vision became still better.

This is a type of many similar cases, and represents a common experience. I cannot understand what advantage, under these circumstances, a non-operative treatment would possess.

If the case is seen late—that is, after the anterior chamber has been reformed owing to the closure of the wound by adhesive inflammation—two courses are open to the surgeon: (a) Compressive bandage, etc., *i.e.*, non-operative, or so-called conservative measures. (b) Abcission of the prolapse, freeing of the wound from adherent and incarcerated iris, paring the wound-edges, and uniting them with a suture; or, if no suture is used, allowing the wound to unite under a compression bandage. Personally, I am governed by the following considerations in the management of this class of cases: If there are no threatening symptoms and no increase in the size of the prolapse, I leave it alone; if, however, there arise irritation from bandaging, ciliary congestion, and increase in the protrusion in spite of pressure, I abscise it, and, in recent years, close the wound with a suture. The following is a case in point:

CASE II.—Joseph P., an Italian laborer, aged about thirty-five, came to the Jefferson Medical College Hospital on May 29, 1896, with a small wound in the lower corneoscleral junction,

¹ Read before the Ophthalmic Section of the New York Academy of Medicine, April 19, 1897.

through which there was a pear-shaped protrusion of the iris and sufficient adhesive inflammation to have closed the wound and restored the anterior chamber. A small amount of ciliary irritation surrounded the lesion. Vision equalled $\frac{20}{100}$. The media were clear and the fundus normal. In spite of a pressure bandage, the iris protrusion continued to grow; hence it was abscised, the edges of the wound pared, two silk sutures introduced, and the patient kept in bed for two days. He was dismissed at the end of the third day with a healed wound, restored anterior chamber, and ovoid pupil, such as one sees in a narrow, downward iridectomy. He continued as an out-patient until the wound was free from irritation, and was not again seen until February, 1897, nearly a year after the original accident, when his eye was perfectly quiet, the scar scarcely detectable, and the vision $\frac{20}{30}$ with correcting glass.

In a number of cases treated by abscission of the prolapse and suture of the wound, I have never seen anything but good results, except in one instance which represents an unusual but not impossible complication. The case has already been reported,¹ but may be briefly referred to:

CASE III.—On the 28th of February, 1896, a girl aged three and a half years, was brought to the Jefferson Medical College Hospital for traumatic hernia of the iris. The child had received an injury of the right eye from a pair of sharp scissors at the corneoscleral junction, through which there was an extensive prolapse of the iris. There was little irritation and the anterior chamber had been restored, but as the prolapse appeared to be increasing, it was abscised. The operation was followed by a smart hemorrhage which filled the anterior chamber. A pressure bandage was applied and the child was put to bed. At the end of twenty-four hours, absorption of this blood had taken place, but partly owing to the extreme restlessness of the patient, successive hemorrhages occurred, and when she was dismissed from the hospital three days later, at the request of her parents, although contrary to our advice, the anterior chamber was so full of blood that all underlying tissues were obscured. One week later there were distinct symptoms of cyclitis, a fine flush surrounding the corneal margin. Under atropin and the internal administration of small doses of calomel this condition subsided. In fact, the cyclitis disappeared, in spite of the fact that in the meantime the child was attacked with measles and passed through the ordinary phenomena of this exanthem. As early as the tenth day after the operation, and very markedly after the attack of measles, we began to notice a discoloration of the cornea. This increased until there was typical blood-staining of the cornea, which caused this membrane to assume a greenish-brown color, with the exception of a small rim, two millimeters in diameter at its circumference.

There is little doubt that the hemorrhage follow-

ing the abscission of the iris was responsible for the blood-staining of the cornea. Whether the condition would have healed promptly and favorably without operative interference is a matter of pure speculation.

II. *Cases of Prolapse of the Iris Through a Wound Extending Nearly or Entirely Across the Breadth of the Cornea, either Vertically or Horizontally.*—These cases, it seems to me, present an entirely different problem from prolapse of the iris at the corneoscleral junction; first, because the prolapse usually is more extensive; second, the underlying structures are more apt to be wounded; and third, the position of the prolapse is frequently such that a mydriatic is able to exert its most favorable influence.

If seen early—that is, before there is marked adhesion between the prolapsed iris and the edges of the wound—it may be possible to replace the iris in whole or in part and keep it in position by pressure, atropin, and dorsal decubitus. If it is not possible to replace it through the entire length of the wound, the central portions of it may be freed with the spatula, while the prolapse at the peripheral end of the wound—that is the one approaching the corneoscleral junction—may be abscised and treated in the same manner as is a prolapse entirely located in this region. These cases must be exceptional, but I have one in mind with good result.

If seen later—that is, when the iris has already become firmly adherent to the edges of the wound and the wound is at all extensive in length—I am inclined to agree with the advice recently recorded by Dr. Knapp, namely, to “treat the case expectantly as long as no threatening symptoms appear.” This treatment, I believe, should be the one already detailed, atropin, or other reliable mydriatic, rest in bed, and compressing bandage. The chief reason for it, in my judgment, depends upon the fact that, in addition to the value of pressure, the favorable physiologic action of atropin or other mydriatics upon the iris is secured in a way that is not obtained when the prolapse is at or close to the corneoscleral junction. The mydriatic rolls the iris back and tends to draw the prolapsed portion from the wound. This is proved by the fact that in many of these cases the iris is drawn out of the incision toward the central portion of the wound, while it remains clamped in the periphery where the drag upon it is less effective.

To be sure, even when the prolapse is solely located in the periphery, there is also some influence exerted by the mydriatic to withdraw the attached iris from its position, an effect, however, which is partly, if not entirely, counteracted by the equal effect of rolling back another portion of the iris toward the prolapse. For this very reason, in the

¹ *Philadelphia Polyclinic*, September 5, 1895.

peripheral cases, it has been the habit of surgeons to employ eserine, with the hope that under the influence of the contraction of the pupil the iris will be drawn from its attached position in the corneal periphery. My experience, however, is that eserine is very apt to increase ciliary irritation, and is not an acceptable drug in traumatic prolapse of the iris. I make exception of a few cases of prolapse after cataract extraction, in which I have seen it act very favorably. Moreover, abscission of an extensive prolapse across the corneal breadth results not in a small, smooth coloboma, but in a more or less unshapely loss of iris tissue. Touching this point, the following illustrative case may be introduced:

CASE IV.—Mary H., a child about one year of age, was brought to the Jefferson Medical College Hospital on March, 24, 1897, with the history that she was struck in the eye with a piece of metal attached to a window blind. The accident occurred four days before her entrance into the hospital. She had been under treatment in another institution, but the parents becoming dissatisfied, they had sought other advice. The wound extended from a half millimeter in the upper ciliary region, in a curvilinear manner, downward across the cornea, terminating a little beyond its middle. The iris was extensively prolapsed and the eyeball congested, but as far as could be seen there was no injury of the deeper structures. The treatment consisted entirely of pressure bandage and atropin, and resulted in a steady subsidence of the prolapse, so that at the present writing the eye is nearly white and quiet, with a small, non-protruding attachment of the iris near the center of the wound, with the indications that it will be entirely withdrawn into the anterior chamber, the drag on the iris by means of the atropin toward the periphery having been sufficient to draw this tissue out of the lips of the wound, except at the point mentioned.

Bacteriologic examination is an important factor in deciding whether or not there should be surgical interference in cases of prolapse of the iris seen late—that is, after closure of the wound by adhesive inflammation. As has been pointed out by Knapp, the surrounding cornea is infiltrated with micro-organisms, although the iritic tissue itself may be free from them. A case in point is the following:

CASE V.—A boy about ten years of age came to me ten days after he was struck in the right eye with a sharp stick, which cut a ragged wound at the inner side of the cornea, extending vertically across its entire breadth. The iris tissue was clamped in the wound and protruding, and a grayish line was manifest about the center of this tissue and extended somewhat into the corneal area. The lens appeared to be partially opaque.

Inoculations from the conjunctiva, which had been frequently washed with a saturated solution of boric acid by the attending physician and had been

cleansed only a short time before the inoculation was made, proved to be sterile. Inoculations from the grayish line previously described, which, it should be understood, was not in the iris tissue itself, but on the surface of the lymph which covered it, and in the surrounding corneal tissue, yielded a perfectly pure culture of *staphylococcus cereus albus*.

Although the child was brought with the expectation of operative interference, advice against reopening the wound and abscising the prolapsed iris was given. The situation of the prolapse was such that the favorable action of atropin could be obtained; there were no marked signs of bandage irritation or ciliary congestion; and opening of the wound would, it seems to me, only have liberated, as it were, staphylococci and presented to them paths for entrance into the deeper ocular structures. Hence, the advice of expectant treatment, with the suggestion that probably later the case would have to be dealt with on the principles which govern the management of traumatic cataract.

III. *Cases of Prolapse of the Iris Through a Corneal or Corneoscleral Wound, Associated with Lesion of the Underlying Structures, Generally the Crystalline Lens.*—Certainly no hard and fast rule can be given to cover all cases, which, however, naturally divide themselves into two chief classes:

1. Those cases in which the lesion is so extensive that conservation of the eye is problematical. With these instances we are not specially concerned this evening.

2. Those cases associated with injury of the lens and followed by opacification and swelling of its tissue. The urgency of the symptoms and the age of the injury must decide action. Some of these cases must be relegated to the class already referred to and illustrated by an example to which expectant and primarily non-operative treatment is suited. In others, both lesions may be dealt with at one sitting.

CASE VI.—For example, in a case not long since under my care, the wound being in the upper portion of the cornea and seen about ten or twelve days after the accident, the lens being opaque and partially protruding into the anterior chamber, a small, upward corneal section was made, the prolapsed iris seized and removed, and the soft lens-matter expressed through the wound. The primary vision, without treatment of the capsule, was $\frac{3}{30}$. Subsequently there was thickening of the capsule and the vision dropped to $\frac{2}{200}$. The patient declined to allow division of the membrane.

Such a procedure, if possible, seems to me more desirable than a primarily non-operative course, for, at all events, operation later on is sure to be needed.

IV. *Cases of Prolapse of the Iris Through a Corneal Wound, with Prolapse of the Ciliary Body or*

Process Through its Scleral Extension.—Under these circumstances, my experience coincides with that recently recorded by Dr. Knapp. The iris portion of the hernia may become quiet, or even withdrawn into the anterior chamber, while the ciliary end of the lesion forms a cyst-like protuberance. Therefore, if I see a case of this character, and it is a proper one for this manipulation, I clear the wound of all protruding ciliary tissue, if I may so express myself, and close it with sutures. These sutures are passed, however, through the conjunctiva overlying the wound and not through the sclera; at least, I am disinclined to pass them through the sclera unless absolutely sure that this can be done without inclusion of any uveal tissue in the stitch.

If the case is seen late, *i.e.*, after the cyst has formed, the latter is excised and the eye treated exactly as after abscission of pouch-like hernias of the iris already described. While it is true, as pointed out by Knapp, that prolapses of the ciliary tissues "are apt to produce cyst-like ectasias which, for their cure, require thorough excision," this rule also meets with exception.

CASE VII.—A girl, aged eleven, came to the Jefferson Medical College Hospital in the early portion of 1896, with the history that one year previously she had been wounded in the right eye with the tine of a fork. Downward and inward in the ciliary region, about four millimeters from the corneal margin, was a small, translucent, cyst-like ectasia, with dark-colored base. The eye was otherwise normal. Complaint was made of pain, watering, and photophobia of the left eye, and, apprehensive of sympathetic trouble, the patient was kept under observation for some time. She then disappeared from view, and was not again seen until the present month—more than two years after the injury, when the cyst, about the size of a small pea, was found in exactly the same condition as at her first visit. In the meantime the refractive error had been corrected, and both eyes were quiet and comfortable.

V. *Management of the Adherent, Non-bulging Cicatrix After Healing of an Iris Prolapse.*—As may have been gathered from what has been previously said, one of the chief advantages of operative interference in traumatic prolapse of the iris, under those circumstances in which I believe it to be not only justifiable, but the best procedure, is the securing of a non-adherent cicatrix. Now, although eyes which have healed without infective inflammation and without surgical interference are usually perfectly quiet, non-irritable organs, in a certain number of cases, the slight drag on the attached iris during the movements of the pupil is the cause of pain and discomfort. Therefore, I would like to add one word in regard to what I may call the treatment of the sequel of prolapse of the iris, that is, of the adherent cica-

trix. Take, for example, the case of the girl detailed, in which the iris prolapsed through a curvilinear wound extending half way across the breadth of the cornea, and was withdrawn into the anterior chamber at all points except one near the center of the scar. At this point the iris was attached and lifted up in a minute tent-like extension, the pupil below it being somewhat ovoid in shape. In cases of this character, I am accustomed to free the attached iris from the scar by the ordinary operation of division of anterior synechia. The method I prefer is the one specially advocated by Mr. Lang of Moorfield Hospital, in which an instrument not unlike the Knapp knife-needle is introduced into the anterior chamber and the synechia divided by a slight lever-like movement. The iris drops back into place, a drop of atropin solution rolls it out of danger of re prolapse, and a circular pupil is secured. It is less easy to accomplish this maneuver, when the iris is prolapsed in the periphery or angle of the anterior chamber, although it can also be done there with the same result. I have never seen harm follow this slight operation, and I have more than once seen an eye thus relieved, which had previously been persistently painful, grow comfortable and quiet.

The question of prolapse of the iris as the result of perforating ulcers of the cornea is not part of the discussion this evening, but it perhaps is not entirely out of place to say that these cases seem to me to demand the same line of treatment as the traumatic ones, and the management of the case is governed by the same principles as those already enunciated. In a few instances where the prolapse has been an extensive one and has protruded through a large, somewhat irregular opening, which could not be neatly coapted with stitches, I have very successfully planted a flap, after the manner of Gama Pinto.

In one instance, associated with the last stage of a gonorrheal conjunctivitis, I took the graft from the opposite or sound eye.¹

With reference to *prolapse of the iris as a complication of the simple extraction of cataract*, my practice is the same, I believe, as that of many surgeons, chiefly Dr. Knapp, namely: If the prolapse is discovered within a few hours after its occurrence, it is cut off and the edges of the iris reduced, exactly as after the operation of iridectomy. If the prolapse is not noted until later, for example, the third or fourth day, it is allowed to remain until the eye is quiet, when, if there is staphylomatous bulging, the protrusion is abscised, or, in other words, treated as is a staphyloma of the cornea.

In a few instances I have inserted after this operation one or two delicate silk sutures, and have been

¹ *Philadelphia Polyclinic*, 1896, vol. v, No. 14.

pleased with the result. Once I have seen the prolapse entirely reduced by the use of eserine, the iris being withdrawn into the anterior chamber and the pupil becoming perfectly circular on the sixth day after the accident.

In the beginning of this paper I said, "Evidently no single rule of surgical conduct is applicable to each case of traumatic prolapse of the iris." But if an attempt to formulate such a rule should be made, which, like all other rules, must meet with exceptions, it would read somewhat as follows: Whenever it is possible to secure clean removal of the protruding tissue operative interference is indicated; when this is not possible non-operative measures, as in the instances already described, are worthy of consideration and adoption.

THE OPERATIVE TREATMENT OF SUPPURATIVE AND NON-SUPPURATIVE MIDDLE EAR INFLAMMATIONS.¹

By EDWARD B. DENCH, M.D.,

OF NEW YORK;

PROFESSOR OF OTOLGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; CONSULTING OTOLOGIST TO ST. LUKE'S HOSPITAL; AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I HAVE so frequently spoken upon the subject to which I now invite attention, that I feel some hesitation in making it the theme of this article. Were it not for the fact that the surgery of the middle ear is still in its infancy, I should scarcely feel warranted in so doing. Being convinced of the great value of middle ear operations, both in suppurative and non-suppurative otitis media, provided proper judgment is exercised in the selection of cases in which such procedures are to be instituted, I take the liberty of again referring to this method of treatment.

Chronic inflammations of the middle ear may be divided into two large classes, first, suppurative inflammation, and, second, non-suppurative inflammation. In suppurative inflammation of the middle ear, operative procedures are demanded for the relief either of a discharge from the ear, or of impairment of hearing which has resulted from a previous purulent process, the otorrhea having ceased spontaneously. A discharge from the ear, of long duration, which has failed to yield to milder measures of treatment, is always indicative of caries within the tympanum. The disrepute into which middle ear surgery, as applied to these cases, has fallen, is largely due to the fact that a careful selection of cases proper for operation has been neglected. When there is extensive caries within the tympanum, and

when this destructive process has extended into the mastoid cells as well, it is evident that the removal of the ossicles only, or in fact any operative procedure through the external auditory meatus, will fail absolutely to relieve the condition. Here a more radical operation, such as the Stacke-Schwartz, is demanded. In a certain proportion of cases, however, we find that the bony involvement is confined either to the ossicular chain or to those parts of the tympanum easily accessible through the external auditory canal. It is in these cases that the removal of the carious ossicles and a thorough curettement of the tympanum effects a complete cure. Statistics show that the percentage of cures following ossiculectomy is about equal to that obtained by the Stacke-Schwartz operation. When we consider that the cases included in these statistics were unselected, the value of the less radical operation is at once demonstrated. A careful reading of the published reports of cases proves that, in many instances at least, an unfavorable result was due simply to an incomplete operation. It is to be remembered that in about eighty-five per cent. of all cases of caries of the ossicles the incus is involved. In a large number of the reported cases, the remnant of this ossicle was not removed, the operator contenting himself by taking away the malleus. The carious incus was allowed to remain in the middle ear, and hence the discharge was not relieved. I have always insisted upon the importance of removing both ossicles to obtain a satisfactory result. If the incus has been partially destroyed the fragment of the ossicle remaining is often difficult to remove. Its extraction prolongs the operation, but is essential if a successful result is to be obtained.

The same rule applies to curettement of the tympanum. The operation should never be looked upon as completed after both the malleus and incus have been excised. Every portion of the middle ear accessible through the canal should be examined either visually or with the probe, and all softened areas should be thoroughly scraped with a sharp spoon. The same instrument should also be carried into the tympanic vault. Run off all softened bone in this region. Conducted in this way an intratympanic operation never fails to diminish greatly the discharge, and in a large proportion of cases, to cause its complete cessation. As the patient is under general anesthesia, there is no necessity for haste at the expense of thoroughness. In my own cases, the operation not infrequently has occupied an hour and a half, most of the time being spent in searching for a small fragment of the incus, and in curetting the intratympanic cavity until all softened bone had been removed.

¹ Read before the Southern Section of the American Laryngological, Rhinological, and Otolological Society, New Orleans, March 3d, 1897.

The technic of the operation effects the result to no small degree. If the middle ear is filled with granulation tissue, this must be removed before any attempt is made to excise the ossicles. In suppurative otitis, the lining membrane of the tympanum is exceedingly vascular, and under the most favorable conditions an incision of the tissues is followed by free hemorrhage. When granulation tissue is present, the hemorrhage may be so profuse as to entirely hide the field of operation. Considerable local treatment may be necessary, therefore, before attempting to remove the carious ossicles, although the necessity for surgical interference may be apparent from the outset. It is not possible to perform a satisfactory operation for intratympanic caries under local anesthesia. The removal of the ossicles may be effected without difficulty, but the pain incident to curetting the middle ear cannot be prevented by any local application.

The proper illumination of the field of operation is also essential, and no one should operate with a poor light. My own preference is the electric light, although an oil lamp or an ordinary gas jet will afford sufficient illumination. The objection to these last two is the possible ignition of ether vapor by the exposed flame, unless the source of light is above the patient and removed at a considerable distance. With proper precautions, however, this danger can be overcome.

The steps of the operation depend largely upon the local condition. When the membrana tympani is almost completely destroyed, and the ossicles are drawn upward into Shrapnell's membrane, the procedure is usually as follows: Any adhesions posterior to the stapes are divided by a sharp-pointed knife inserted between the head of the stapes and the tympanic ring, provided the former landmark is visible. When this cannot be seen, the knife is introduced close to the posterior margin of the tympanic ring, just above the normal situation of the stapes, and is carried inward until its point impinges upon the internal wall of the middle ear. The knife is then carried downward for a distance of about one-twelfth of an inch, completely dividing all soft tissues. After this incision, the head of the stapes will often be recognized, presenting as a small white spot close to the border of the tympanic ring, the tension of the adhesions between the anterior crus and the adjacent wall of the oval niche being sufficient to pull the ossicle forward. An angular knife is then introduced in front of the stapes to free this ossicle from the incus. The long process of the incus has usually been destroyed in these cases, but it is advisable to take this precaution to prevent the possible evulsion of the stapes

when the incus is removed. The next step is to free the malleus by the division of the anterior, posterior, and external ligaments. This is done by carrying the incision from the anterior and posterior margins of the perforation completely about the malleus over the short process. It is well to cut first in front of the malleus from the superior border of the perforation, upward to the short process, and to make a second incision, in a similar manner, posteriorly, the incisions meeting above the short process.

The division of the external ligament is somewhat difficult on account of its density. It is best effected by plunging a strong sharp-pointed knife upward and inward into the tympanic vault just above the short process of the malleus, and dividing the dense bands anteriorly and posteriorly. If the manubrium is adherent to the internal wall of the middle ear, it may be separated by the use of the angular knife.

The malleus is then grasped just above the short process, and is first pushed inward to dislodge the head from the shelf-like process upon which it rests, after which it is drawn downward and outward. Occasionally, when the caries has not been extensive, the incus may be seen as soon as the malleus has been extracted, and the hemorrhage may be controlled by cotton pledgets. The part presenting is usually the long process or the portion of it which remains. It usually lies close to the posterior margin of the tympanic ring, projecting slightly beyond this. The incus-hook is then introduced into the canal and passed behind the posterior margin of the ring, the concavity of the instrument being directed forward. The instrument is then carried upward, and at the same time is rotated forward so as to displace the incus into the field of vision. As soon as this is accomplished it is grasped by the forceps and easily removed. It is important, however, not to attempt extraction when only a small portion of the bone is visible. If the operator fails to grasp the bone firmly, it is frequently displaced into a remote corner of the tympanic vault, and it is found only with the greatest difficulty. A little careful manipulation at this stage of the operation may save a great deal of time. It should be borne in mind that the incus does not lie close to the internal tympanic wall, but near the tympanic ring, its short process resting upon a ledge of bone just above the superioposterior margin of the meatus.

Failure to extract the incus is often due to the fact that the incus-hook is passed too far into the tympanic cavity, and when rotated forward lies to the inner side of the ossicle, and consequently fails to displace it. It is better to introduce the hook just

within the tympanum and then to draw it outward until its angular extremity engages the tympanic ring. The subsequent manipulation is performed with the hook constantly in contact with this bony ring, and of necessity it must displace the ossicle if it is in its normal situation. While the hemorrhage may be rather profuse during the entire operation, it may usually be controlled by firmly packing the canal with small pledgets of cotton. These pledgets are allowed to remain in position for one or two minutes, and when removed the field of operation is usually found to be perfectly dry. The deepest plug may be pressed firmly against the internal wall of the middle ear without danger of displacing the stapes, the walls of the oval niche sufficiently protecting the ossicle.

To thoroughly remove carious bone from the tympanic vault, curettes of various sizes are necessary, the cutting portion of the instrument being placed at right angles to the shank. These curettes are made to cut both forward and backward, and should be used freely in every portion of the tympanum not visible through the speculum. The internal wall of the atrium should also be thoroughly curetted. Here the sense of sight aids us in discovering the carious areas.

It is to be remembered, even in the selected cases, that the surgeon should not give a too favorable prognosis as to the complete suppression of the aural discharge following such an operation. He can certainly promise that the discharge will be greatly diminished in quantity, and will be so slight as to cause no inconvenience; and he may confidently anticipate a complete cure in many instances if due care is taken to operate only on suitable cases. One of the most important arguments in favor of such a procedure is the establishment of perfect drainage through the external auditory canal. For this reason, intracranial infection cannot occur, and the danger incident to the suppurative process within the middle ear is then entirely avoided. I append the statistics of my own operations:

Operations for Otorrhea.—Ossiculectomy, 61 cases. Cured, 35; improved, 17; under treatment, 1; result unknown, 8; hearing made worse in a single case. Stacke-Schwartz operation, 10 cases. Cured, 6; improved, 4.

The effect of such an operation upon the hearing must always be taken into consideration, and no patient should be subjected to operation until a careful functional examination has been made. In a few instances the hearing has been impaired by the operation; in the great majority, however, the hearing is very greatly or moderately improved, or remains the same as before operative interference. The following statistics show the results obtained in

my own cases: Operations for improvement of hearing when slight otorrhea was present, 26 cases. Ossiculectomy performed in 22 cases. Improved, 17; unimproved, 5. Synechiotomy performed in 4 cases, all improved.

A certain proportion of cases is met with in which the suppurative process has undergone a spontaneous cure, and the surgeon is consulted as to the possibility of improving the function of the organ. Some of the most gratifying results obtained in aural surgery follow operative interference in these instances. The intratympanic condition is very similar to that found in hyperplastic inflammation of the middle ear. When a functional examination shows that the perceptive apparatus has not been involved secondarily, the hearing can almost certainly be improved by the division of adhesions which interfere with the mobility of the ossicular chain. In this connection it is to be remembered that any increased tension in one ear will sooner or later impair the function of the other. For this reason it is the imperative duty of the otologist to relieve the tension of the conducting apparatus in order to preserve the integrity of the opposite ear. Ordinarily the tension can be relieved by exceedingly simple measures, and the removal of the two larger ossicles and of the remnant of the drum-membrane is seldom necessary. My own rule in these cases is first to divide any adhesions between the posterior crus of the stapes and the adjacent wall of the oval niche. The stapes should then be completely separated from the long process of the incus either by disarticulation at the incudostapedial joint, if this is still intact, or by division of connective-tissue bands which may have formed after the disintegration of the descending ramus of the incus. The stapes is freed from adhesions, above, below and in front, and is cautiously mobilized by pressing it in various directions with the cotton-tipped probe. In attempting to mobilize the stapes, any undue violence must be avoided as the crura may be easily fractured if too much force is employed.

The transmission of sonorous vibrations to the labyrinthine fluid can only take place when both the stapes and the covering of the round window are fairly movable. Although the stapes may be mobilized, sound perception may still be absent. The same process which has caused the rigidity of the stapes may have produced a similar condition of the membrane of the round window. To restore the integrity of the apparatus these adhesions must be divided. To do this, an angular knife is passed into the niche of the round window and is then rotated from below upward so as to sever any adhesions which may be present. Firm pressures upon the

knife is necessary in order to accomplish the desired result. There is no danger of wounding the membrana tympani secundaria as, from its position, it lies in nearly the same plane as the blade of the knife.

While the procedure, as described above, may seem visionary, the results obtained constitute the proof of its practical value. I would not be understood as saying that it is possible in every case to secure a favorable result by a single operative procedure. In order to restore the equilibrium of the stapes and to enable it to perform its function in the best possible manner, repeated operations may be necessary. It is important to test the hearing frequently in order to ascertain the result of each successive synechiotomy. In connection with the quantitative tests it is also important to determine the lower tone limit, as this should fall steadily as the conducting apparatus is rendered less rigid. Operative procedures about the stapes may immediately be followed by an impairment of the hearing on account of the formation of blood-clots, or because of the reaction incident upon such measures. A considerable interval should therefore be allowed to elapse before the patient is subjected to a second operation in order that the parts may return to their normal condition.

Great patience on the part both of the surgeon and the patient is necessary to secure a successful result; but if this rule is followed both will feel amply repaid for their persistence.

The author's results are as follows:

Otitis Media Purulenta Residua.—For improvement of hearing, 20 cases. Synechiotomy performed in 18—17 improved, 1 unimproved. Ossiculectomy performed in 2 cases—1 improved, 1 unimproved.

In conjunction with operative measures, it may not be amiss to call attention to the mechanic treatment of defective audition in the residual suppurative cases. This term includes those cases in which the suppurative process has run its course and has undergone spontaneous cure. We have then simply to deal with the results of a former suppurative process instead of an active purulent inflammation.

The author claims no credit for original investigation in this line. The use of certain mechanic devices to replace the drum-membrane was employed by the earlier otologists. So far as I know, Dr. Clarence Blake of Boston was the first to use a pledget of sterilized cotton moistened in borated vaselin for this purpose. In many of the residual suppurative cases, when a small perforation exists in the lower portion of the drum-membrane, or when there is a perforation of considerable size in the

posterior and upper quadrant which exposes the head of the stapes, the hearing can often be improved by the application of a pledget of sterilized cotton in such a way as to either close the perforation or to press upon the head of the stapes. In the latter instance the efficacy of the cotton disc depends upon the presentation of a larger surface to the sound vibrations, in this way augmenting the impulse conveyed to the labyrinthine fluid. In many cases the improvement following the use of this simple device is astonishing. It would at first seem that the patient must be constantly under the care of the surgeon in order to derive any benefit from this method of treatment. The patient himself, however, soon learns to apply the cotton pledget. As soon as he is conscious that the pledget has become displaced he syringes the ear, removing the former pledget, and then inserts a new one, the increased power of audition enabling him to recognize the fact that the artificial drum is correctly placed. In fact, patients who have followed this treatment for some time become more expert in executing this manipulation than the surgeon himself.

When we come to the consideration of the non-suppurative form of the inflammation, and the operative measures which are deemed advisable for its relief, the same care must be observed in making a proper selection of cases subjected to operation. I am not infrequently requested to operate upon an ear because it is absolutely worthless and consequently cannot be injured. Unfortunately, many accept this view in selecting their operative cases, and it is for this reason that middle ear surgery has so few advocates. No argument seems necessary to prove the utter absurdity of such a practice. A careful functional examination will always enable the surgeon to determine whether the labyrinth is involved or whether the disease is confined to the middle ear. In the former instance surgery is of no avail; in the latter it almost invariably promises a certain amount of relief. In a few cases the results of functional examination may not be conclusive, and in such an event it is always advisable to open the tympanic cavity by turning down a flap of the drum-membrane so as to ascertain the extent of the middle ear lesion, and to determine to what degree it causes the impairment of function. Such an operation is easily performed under cocaine. A large flap of the membrana tympani may thus be reflected downward and forward, exposing the upper posterior quadrant of the tympanum. The stapes may be separated from the other elements of the ossicular chain and freed from adhesions in the manner already described. If the tests are repeated, we are able to exactly determine the importance of the

middle ear lesion; if there is no improvement, the flap may be replaced and the ear restored to its original condition. On the other hand, the labyrinthin involvement may be of less importance than was at first supposed, in which case the two larger ossicles, together with the membrana tympani, may be removed and the improvement following the exploratory tympanotomy be maintained.

An example of this occurred in one of my own cases. The history of the case led me to believe that the labyrinthin involvement—of which there was decided evidence on functional examination—was dependent upon a pre-existing middle ear lesion. After an exploratory operation, the hearing was markedly improved, and on the following day the operation was completed. The result was eminently satisfactory. The hearing in the ear operated upon was considerably improved, while the effect upon the opposite ear was even more noticeable. Before the operation, the impairment in hearing had been so considerable as to deter the patient from performing his ordinary social duties. At the present time he experiences no difficulty in mingling in society, and the slight impairment in hearing from which he suffers is not apparent.

Any inflammatory reaction following an exploratory tympanotomy invariably results from imperfect technic. With a sterile field of operation, clean instruments, and proper attention to asepsis during the operation, no inflammatory reaction occurs. If the operation is to be completed, *i. e.*, both the membrana tympani and the two larger ossicles removed, the technic is, briefly, as follows: A small pledget of sterilized cotton saturated in a sterilized twenty-per-cent. solution of cocain is introduced through the exploratory opening to secure anesthesia. When the parts are no longer sensitive, a sharp knife is made to puncture the drum-membrane at its inferior pole, close to the tympanic ring. A blunt-pointed knife is inserted through this perforation, and the membrana tympani is divided anteriorly as close to its attachment to the ring as possible as far as the anterior fold. If perfect anesthesia has not been obtained, the operator should immediately stop and apply a cocain solution to the margins of the incision so that the procedure will be entirely painless. The drum-membrane is then divided in the opposite direction until the entire membrana tensa is detached from the tympanic ring. It is then wise to insure complete anesthesia of the upper portion of the tympanic cavity by several applications of cocain by means of a cotton-tipped probe. By winding the cotton firmly upon the applicator, and then bending the pledget at a right angle, it is possible to introduce the instrument for a considerable distance into the tympanic

vault, so that the division of the deeper tissues may be accomplished without pain. The probe-pointed knife is then introduced just below the posterior fold and is carried upward, dividing the posterior ligament and the posterior part of the external ligament. In the same manner the attachments to the malleus are divided anteriorly. It is seldom possible to unite these two incisions above the short process of the malleus, a small strip of the membrana flaccida still remaining intact. To completely free the ossicles, it is most frequently necessary to carry a strong, sharp knife upward and inward into the tympanic vault, directly over the short process, dividing the remaining fibers of the external ligament and the overlying part of Shrapnell's membrane. In some instances the tensor tympani muscle will displace the malleus forward as soon as these ligaments have been divided, and render its seizure with the forceps difficult. In such an event, an angular knife should be introduced behind the shaft of the malleus, and made to sever the muscle by rotating the instrument backward. The ossicle is then grasped near the short process with a pair of strong forceps, and extracted in the manner previously described in detailing the technic in suppurative cases. The incus is then removed, as already stated, this step of the operation ordinarily being less difficult than in suppurative cases. After thoroughly drying the parts, the usual dressing is applied.

After an operation upon the middle ear, it is impossible to prevent the formation of a blood-clot within the tympanum. In suppurative cases the presence of the clot interferes with free drainage, and in non-suppurative cases acts as a foreign body, causing a certain amount of inflammatory reaction. To avoid the formation of a clot, a long, narrow pledget of cotton should be carried into the meatus as far as the fundus. This will act as a drain, and prevent the accumulation either of blood or of inflammatory products within the canal. The distal extremity of the pledget is folded upon itself at the entrance of the meatus, so that it cannot be displaced by the patient. The canal is then occluded by a large pledget of sterilized cotton. As soon as this becomes saturated, it may be changed by an attendant, or even by the patient himself. The deep drain is removed twenty-four hours after operation. The canal will then be found to be perfectly free, and all portions of the middle ear can easily be seen upon speculum examination. It is seldom necessary to introduce the deep drain a second time, all hemorrhage usually having ceased at the end of twenty-four hours. I consider this procedure as one of great importance, both in suppurative and non-suppurative cases.

It is wise to change the dressing daily until the middle ear is perfectly dry. In many cases, however, this is impossible, and an interval of two or three days may be allowed to elapse between the dressings. The only possible accident which may occur is the infection of the middle ear through the canal. To avoid this, all instruments used in dressing the wound should be carefully sterilized. If the walls of the meatus are covered with a serosanguinous discharge, they should be thoroughly dried by means of cotton pledgets, after which the canal is wiped out with a solution of bichlorid of mercury in alcohol, of a strength of 1 to 3000. A little boric-acid powder is then dusted over the walls of the meatus to maintain the parts in an aseptic condition, and to counteract the possibly injurious effects of heat and moisture following the occlusion of the canal. Ordinarily, the reaction following the operation disappears at the end of four or five days, the middle ear being perfectly dry and the mucous membrane presenting no evidences of hyperemia. The precautions alluded to in the early part of this paper are to be observed in order to avoid any possible danger of infection.

The results obtained in my own cases are given below:

Chronic Non-suppurative Otitis Media.—Removal of malleus, incus and drum-membrane, and mobilization of stapes: Cocain operations, 46: Greatly improved, 26; moderately improved, 14; unimproved, 6. Ether operations, 13: Greatly improved, 2; much improved, 5; moderately improved, 5; unimproved, 1. Total, 59 operations; improved, 52; unimproved, 7.

CLINICAL MEMORANDUM.

REPORT OF AN OPERATION FOR THE RELIEF OF COMPLETE PROCIDENTIA OF THE UTERUS AND BLADDER.¹

By H. O. WALKER, M.D.,
OF DETROIT, MICH.

MRS. I. ST. C., aged thirty-two years, weight 90 pounds, was admitted to St. Mary's Hospital, Detroit, January 3, 1897, with the following history: Her father and one sister died of consumption; the remainder of the family are healthy. At the age of fifteen she was married, and a year later gave birth to a child, which died at the age of six months. Shortly after the death of the child she contracted syphilis, again became pregnant, and aborted at the end of the fifth month. In her eighteenth year she joined a circus, and did a great amount of horseback riding and trapeze performing, which line of work she followed

for two seasons, then being compelled to discontinue it on account of severe pelvic pains. There was marked dysmenorrhea and painful defecation, together with occasional attacks of diarrhea. For the past fourteen years she has followed the avocation of waitress and seamstress. She had acquired the opium habit, taking as much as half an ounce of the tincture during twelve hours for the relief of rectal tenesmus.

Physical examination revealed a complete prolapsus of the uterus and bladder, and an exaggerated rectocele. The labia majora were greatly enlarged and of a dense fibrous feel, the condition probably being that known as syphilitic elephantiasis. The labia minora were also considerably hypertrophied. There was an eversion of the rectum, and a fistula upon the right side extending into the rectum about two and one-half inches from the anus. At this point there was present also a rectal stricture which scarcely admitted an ordinary sized lead-pencil. The sur-

FIG. 1.

Complete Procidentia of Uterus and Bladder. Before operation.

rounding parts were greatly excoriated by the discharges from the rectum and fistula. Figure No. 1 gives a fair representation of the condition.

On January 13th, I operated in the following manner: First, I performed vaginal hysterectomy, which necessitated the greatest care to avoid wounding the bladder or rectum. No clamps were used, the arteries being tied with catgut as they presented. I then dissected up the thickened mucous membrane and removed it by elliptical incisions, commencing at the meatus above and keeping close to the labium on each side down to the upper border of the everted rectum. The cut edges were approximated with interrupted silk-worm-gut sutures, leaving an opening two-thirds of the way down for such drainage of the peritoneal cavity as might be necessary. Forcible dilatation, with proctotomy of the rectal stricture, was then done,

¹ Abstract from a paper on "Abdominal Surgery with Specimens," read at a meeting of the Michigan State Medical Society, held at Grand Rapids, May 13, 1897.

and all the parts except the peritoneal cavity were liberally irrigated with 1-1000 bichlorid solution, then thoroughly dried with sterilized gauze, the rectum packed, and the usual dressing applied and held in position by a large sized T-bandage.

Owing to the frequent evacuation of the bowels and the necessity for catheterization, the frequent removal of the dressings and their reapplication was required. The drainage tube was removed on the third day. The future history of the case was uneventful, the temperature never going above 100° F., at any time. At this writing the patient is able to walk about and do light work, the only trouble being some rectal incontinence. Liberal administration of the iodids was resorted to at intervals during the progress of the after-treatment.

Two methods of surgical treatment presented themselves as being applicable to the relief of this poor woman's condition, namely, the one adopted, and the other an ab-

FIG. 2.

Complete Procidentia of Uterus and Bladder. After operation.

dominal section and the fastening of the uterus to the abdominal wall. I questioned the feasibility of the latter method, owing to the numerous adhesions existing and the extensive hypertrophy of the parts. The method resorted to has certainly justified the effort. Figure No. 2, from a photograph taken about a month ago, represents her present condition.

MEDICAL PROGRESS.

The Results of Kocher's Operation for Hernia.—In the *Centralbl. für Chirurgie*, May 15, 1897, KOCHER gives the results obtained by himself and his assistants in 197 operations for the radical cure of hernia. In the operation, as performed by him, the cord at its exit from the external ring is separated, and after division of the cre-

master and the tunica vaginalis, the sac is isolated as high up as possible, and is drawn outward through a small opening in the fascia of the external oblique muscle one-half an inch above Poupart's ligament and one-half to one inch externally to the region of the internal ring. If the sac is large, and on account of its funnel shape a recurrence is feared, a small opening is made into the peritoneal cavity to the outer side of the internal ring, and a curved clamp is passed through this opening and down to the lowest limit of the sac. When it is withdrawn, the sac is inverted like the finger of a glove and drawn outward through the incision, tied, and cut away. The incision is closed by a couple of stitches through muscle fascia. Of the 197 cases operated upon, primary union was obtained in 91.3 per cent. All but twenty of the patients were over fifteen years of age. Of 111 cases, which could be followed, there were four recurrences, that is, 3.6 per cent. No patient died from the operation.

Vitality of the Uterine Mucous Membrane.—JUNG (*Centralbl. für Gynäk.*, May 8, 1897) had an excellent opportunity to observe the remarkable vitality of the mucous membrane of the uterus in the case of the wife of a man treated for gonorrhea and syphilis. She had had seven children and four miscarriages, and on account of profuse and repeated hemorrhages, her uterus was curetted and touched with carbolic acid. The good effects of this treatment had worn off in a month, and the cervical canal was dilated and the cavity of the uterus filled with a paste made of one part of chlorid of zinc and two parts of rye flour. The result apparently was a perfect one, the treatment reducing the size of the uterus, and obliterating the cervical canal. However, in three-months' time the patient was back again complaining of the same old trouble. The uterus was then removed, and examination of its nearly obliterated cavity showed a regeneration in part of its mucous membrane, the new epithelium showing the same pathologic changes as the old layer.

Stone in the Bladder Broken Spontaneously.—SEVEREANU (*Centralbl. für Chirurgie*, May 8, 1897) mentions a unique case in which a stone in the bladder was broken spontaneously. The patient was a man, aged eighteen, who suffered from his second until his ninth year from symptoms of stone in the bladder. From his ninth year until three months before his entrance into the hospital, he was perfectly well and could run and ride without the least pain. One night he fell into a grave and experienced immediate and severe pain in the lower part of the abdomen with a return of the old bladder symptoms. There was no blood in the urine.

By examination through the rectum, and by means of instruments, the bladder was found to contain at least two calculi which moved one upon the other. Suprapubic cystotomy was performed and the two halves of a calculus, which together weighed about an ounce, were removed. Each presented a broken surface which fitted exactly into that of the other half so that there was no doubt that a single stone had been broken into two parts by the fall, possibly, as a result of a powerful contraction of the bladder. The calculus was composed of urates.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JULY 3, 1897.

THE BILL BEFORE CONGRESS ABOLISHING ANIMAL EXPERIMENTATION IN THE DISTRICT OF COLUMBIA.

THIS is not the official title of Senate Bill No. 1063, but indicates the intent of its originators in framing it, as well as the practical effect of its execution. The bill, as originally worded and in its present form before Congress, has all the silky softness of a kitten's paw to the casual observer; but sharp and vigorous claws lie concealed within its insinuating fairness, which await only the legalization of its provisions to assert themselves in their destructive work. The measure is entitled "A Bill for the Further Prevention of Cruelty to Animals in the District of Columbia," and it is in this harmless guise that the Humane Society of Washington is endeavoring to usurp to itself the power of controlling all animal experimentation, not only in the Government laboratories, but also in those of the medical schools and of private individuals. The advocates of the bill are most specious in their arguments in favor of abolishing imaginary cruelties of a most horrifying character and preventing their occurrence by means of carefully issued licenses and a system of regular and

irregular inspection. The harmful character of the bill, as an entering wedge in the hands of visionary enthusiasts destined to prevent all animal experimentation, and so striking at the root of all progress in organic medicine, has been clearly pointed out by the scientific members of the medical profession resident in the city of Washington. This view of the measure has been confirmed by numberless memorials to Congress from all the prominent medical and scientific gatherings which have convened in this country for the last two years, and yet the measure is constantly gaining in strength and steadily approaching the goal of its final passage. It is one of the many illustrations of the fact that a small association of persistent individuals, especially if it contains within its number a few visionary women, can, by gaining the adherence of two or three strong advocates, carry almost any measure through any State Legislature or even through the National Congress, unless it is met and opposed by some scheme of what is known as practical politics. "Practical politics" means the control of a certain number of votes.

Up to the present time, the great brotherhood of medicine and allied sciences has rested upon the belief that its opinions carried weight with the politicians, because it believed the politicians had respect for the opinions of men who must know more upon the subject under discussion than anyone else. Medical societies have therefore contented themselves with simply embodying their opinion in the form of resolutions and presenting them to Congress. It is becoming daily more clear, however, from the progress of this matter, that he who counts upon a politician taking up a cause and throwing the weight of his influence and effort into the fight in its behalf, is certainly reckoning without his host. Sad though the conclusion may be, there no longer exists in our legislative halls a single champion of truth for truth's sake, or of justice for the sake of right. The sooner the medical profession acts in accordance with this understanding, the sooner will it be able to accomplish its end, in caring for the welfare of the community as well as its own safety and progress. Every question before Congress must be put upon the basis of practical politics. In the question at issue, the medical profession is practically unanimous in its opinion of the harmfulness of the pending measure. The only way to make that influence tell, is for

each and everyone of the one hundred thousand physicians in this country to write a letter to his representative and senator in Congress, notifying him that the medical profession takes issue with every representative or senator who does not oppose by his voice and vote this harmful bill. Certainly, there is no question before Congress designed to come home personally to each member of the profession in so harmful a way as this one. The touchstone of his support in the re-election of a member of Congress should be the attitude that member has exhibited toward this bill, and every candidate should be made to know and feel it.

This is a question in which no personal jealousies need enter. Now is the opportunity for the profession to stand shoulder to shoulder for once in a persistent and consistent fight until the desired end is won. Let the country and the world witness a united effort by the whole body of the medical profession to insist upon the right which they feel is theirs, and in the enjoyment of which rests the progress of medicine, and future struggles of this nature will be less arduous and less prolonged.

BALDNESS, TUBERCULOSIS, AND ARSENICAL INTOXICATION.

In November, 1896, the attention of the readers of THE MEDICAL NEWS was directed to Sabouraud's studies of alopecia areata. In their course he was led to the investigation of other forms of loss of hair, and now in the *Annales de Dermatologie et de Syphilographie*, 1897, viii, 257, he gives us a most original and valuable paper on ordinary alopecia. He believes that the same microbe he found as the probable cause of alopecia areata is the cause of ordinary alopecia. This is an unexpected discovery, but he is so sure of his ground that he ventures to say the same microbe is the cause of loss of hair under all conditions, though he would doubtless except accidental causes. He is free to admit that there are still many unanswered questions in regard to loss of hair which the discovery of his microbe does not answer, but he thinks the answer will be forthcoming in due time.

The course of events in the production of cavities is as follows: There is an invasion of one or more hair-follicles by the microbe which develops its peculiar nest below the surface of the skin and above the

opening of the sebaceous gland into the hair-follicle. Its presence excites the sebaceous gland to a more active production of sebum, in consequence of which there are found upon the scalp the fatty plates so well recognized as seborrhea sicca. At the same time an inflammation takes place about the hair-follicle, the nutrition of the hair is interfered with, and after a time the hair is shed. The growing new hair may push out the microbial nest, and no permanent damage be done. Should a second infection of the follicle take place, permanent damage is apt to result, the follicle producing hairs of lesser and lesser diameter, until at last the papilla is destroyed. Follicle after follicle becoming diseased, we have the well-recognized bald patch. After years, the microbes in the follicles undergoing a steady increase in number, and the inflammation becoming chronic, atrophy of the scalp results, with a smooth, varnished bald head as a sequel. Unless the progress of events is checked by energetic treatment, permanent destruction of the hair is certain.

The author explains the different clinical pictures of alopecia areata and of alopecia vulgaris by assuming that in the former all the follicles of an area are affected, while in the latter only a follicle here and there is invaded. These investigations of Sabouraud deserve repetition by other observers, and without doubt will receive their deserts. While some of the phenomena of loss of hair are explained by his findings, it seems to me that some of his dicta are too sweeping. What with Sabouraud's findings and those of other observers, the preponderating influence of seborrhea or seborrheal dermatitis in the production of baldness must be recognized in the near future. This being established as a fact, it must follow that the occurrence of dandruff will be taken out of the category of slight and trivial ailments that are to be left alone, and the importance of active antiparasitic treatment of all such cases will impress itself on doctors as well as laymen, greatly to the benefit of the growing generations.

The medical mind has of late become actively engaged with the question of tuberculosis. While all physicians are aware that the tubercle bacillus invades the lungs and gives rise to pulmonary tuberculosis, there are comparatively few who dream of the number of diseases of the skin which are due to the same cause. Hallopeau (*Annal. Derm. et Syph.*,

1896, vii, 1007) says that the reason there are so many varieties of tuberculosis of the skin is found: In the complex structure of the skin, the different elements of which react differently under the influence of tuberculous infection; in idiosyncrasy of patients, and in the differences of the infective agent, whether it is the bacillus or some form of toxin developed from it. He describes the following tuberculous affections: Tuberculosis verrucosa cutis, anatomic tubercle, tuberculous gumma, tuberculous tumors, tuberculous ulcers, tuberculosis suppurativa, lupus vulgaris and erythematosus and lupus pernio. Besides these diseases, due more or less directly to tubercular infection, there are a number of dermatoses which occur in tuberculous subjects, such as lichen scrofulosorum, acne scrofulosorum, tuberculous erythemas, and a group of diseases recognized by the French under the title *folliculites suppuratives disséminées ou agminées*. In the limited space at my command, I can only draw attention to the subject, leaving the reader to consult for more detailed information the most recent treatises on dermatology.

The drug most extensively prescribed without discrimination by general practitioners in the treatment of skin diseases is arsenic. The more a man knows about dermatology, the less he uses arsenic. Like a host of drugs, it has at times disagreeable incidental effects. L. Nielsen, writing about arsenic (*Monatshefte f. prkt. Dermatol.*, 1897, xxiv, 137), says that arsenical pigmentation is one of the earliest and best known of the incidental effects, showing itself as brown spots, either occupying the sites of the lesions of the disease for which it was administered, or without any previous eruption. In the latter case it is often combined with other symptoms of intoxication and with keratosis. The pigmentation may occur both with acute and chronic poisoning. Idiosyncrasy exercises great influence in its production. It may appear after weeks, months, or years of more or less continued ingestion of the drug, the amount necessary to cause it varying greatly. Erythema often precedes its appearance. It may begin as very small round pigmented spots, or as coin-shaped, more or less sharply defined macules, and most often is widely diffused. The color may be dirty gray, but is usually some shade of brown. It is most pronounced about the neck and those regions physiologically most pigmented.

The affected parts are at the same time dry, rough, and scaly. The mucous membranes may be affected. It usually disappears a few weeks or months after stopping the drug, but it may continue indefinitely.

Keratosis comes on usually after prolonged use of the drug, and is more frequent in men than in women. It is symmetrical, and usually involves both the palms of the hands and soles of the feet. It may be diffused over the whole palm or sole and spread along the sides of the toes and fingers, though the middle of the palm and the concave part of the sole may be spared. Exceptionally it may affect the back of the hand or foot. Patches have occurred on the breast and abdomen, and between the shoulder-blades. Corns constitute the localized form of keratosis. They are multiple, numerous, small, diffused, or crowded together. They occur in the same locations as do the diffuse form. They are hard and warty-like, yellowish brown or darker. Keratosis may be combined with erythema, itching, hyperidrosis, deformity of the nails, or symptoms of inflammation. Epitheliomata may develop either from the corns or the diffused keratosis.

GEORGE THOMAS JACKSON, M.D.

ECHOES AND NEWS.

New Volume of Hare's System of Practical Therapeutics.—Messrs. Lea Brothers & Co. announce that a new volume of Hare's System of Practical Therapeutics will be issued shortly.

Dr. Charcot's Statue.—The statue of Dr. Charcot by the sculptor Falguière is nearly finished, and will soon be erected in the Salpêtrière Hospital, where Charcot made his experiments on hysteria and hypnotism.

Obituary.—Mr. J. Greig Smith, M.B.C.M., F.R.C.S., professor of surgery in University College, Bristol, England, died suddenly from pneumonia June 1st. Mr. Smith was known in America by his classic book upon abdominal surgery.

The First International Exhibition of Dentistry and Dental Surgery.—An international exhibition of dentistry, dental surgery and hygiene, under the auspices of a committee having among its number many competent experts, will be held in September at the Marlborough Hall, Polytechnic Institute, Regent Street, London.

Yellow Fever at New York Quarantine.—Isolated cases of yellow fever are constantly being discovered on ships from Central American ports. Ten cases have occurred during the past two months. The careful quarantine pre-

served in New York harbor has been successful in preventing any cases entering the country.

Address in Medicine at Yale University.—The annual address in medicine before the Medical Department of Yale University was delivered on June 29th at New Haven, Conn., by Dr. William M. Polk of New York. The subject of the address was "How to Work." In the evening a reception was tendered Dr. Polk by the faculty of the university at the residence of Professor William H. Carmalt.

Ice Cream as a Cure for Hiccough.—A serious case of hiccough in a boy, aged seventeen years, living in Westchester County, N. Y., has recently been reported. After resorting to various approved remedies without success for two weeks, the attending physician prescribed ice cream *ad libitum*. After two days of this treatment the hiccough ceased, and the patient gradually recovered from his emaciated condition.

An Autopsy Club in Chicago.—It is reported that a club has been formed in Chicago, the *sine qua non* of whose membership is that each member when he dies shall leave his brain to be thoroughly investigated by the active members of the organization. It has been suggested that the deep mystery that has hung over the mental operation of Chicago people promises to be swept away, in the course of time, by this system of investigation.

Colorado's Contribution to the Rush Monument Fund.—Colorado has already fulfilled the pledge for a \$2000 contribution to the Rush Monument Fund, made by Dr. Graham at the meeting of the American Medical Association at Philadelphia. At the meeting of the State Medical Society, June 15th, the full sum pledged by Dr. Graham was immediately raised by individual subscriptions, offered most generously and with great enthusiasm.

A Memorial to Dr. Samuel Fisk Green.—A hospital erected to the memory of Dr. Samuel Fisk Green, a brother of the Hon. Andrew H. Green of New York, has recently been opened on the island of Caradive, Ceylon. Dr. Green resided in Ceylon for twenty years, during which time he published a series of elaborately illustrated works, now the standard medical literature in the Tamil language. The opening of this hospital and the introduction of modern methods mark the beginning of a new epoch in the history of medicine of that country.

Mississippi Valley Medical Association.—The next meeting of the Mississippi Valley Medical Association will be held in Louisville on October 5, 6, 7, and 8, 1897. The president, Dr. Thomas Hunt Stucky, and the chairman of the Committee of Arrangements, Dr. H. Horace Grant, promise that the meeting will be the most successful in the history of the Association, and this promise is warranted by the well-known hospitality of Louisville and Kentucky doctors. Titles of papers should be sent to the secretary, Dr. H. W. Loeb, 3559 Olive street, St. Louis.

Announcement.—A letter from the Secretary-General of the Twelfth International Medical Congress to Dr. A.

Jacobi, the Chairman of the American National Committee, conveys the following information, which is additional to that which has been published in the medical journals: As it is too late to send tickets to the American congressists, they are requested to send to the Secretary-General at Moscow their addresses in London, Berlin, Vienna, or Paris, or to avail themselves of the National Committees in those cities, in order to receive their tickets and free passes over Russian railroads in those places. The free passes are valid from July 13th to September 13th over the following routes: Eydtkunen to Moscow and back; Moscow to Petersburg, or Moscow to Graniza, or Moscow to Odessa; or *vice versa*, Graniza to Warsaw, or Moscow, and return by Moscow to Petersburg (or Odessa, or Eydtkunen, or Ungheni, or Alexandrow), or *vice versa*. Different lines going and returning may be chosen, and stop-over is permitted. Eydtkunen to Petersburg is excluded from the free list.

Bacteriologic Examinations of the New York City Board of Health.—In order that the value of bacteriologic examination of the sputa may be at the service of physicians in all cases not under treatment in hospitals, the Health Department is prepared to make such bacteriologic examinations for diagnosis, if samples of the sputa, freshly discharged, are furnished in clean, wide-necked, stoppered bottles, accompanied by the name, age, sex, and address of the patient, duration of the disease, and the name and address of the attending physician. Bottles for collecting sputa, with blank forms to be filled in, can be obtained at any of the drug stores now used as stations for the distribution and collection of serum tubes for diphtheria cultures. After the sputum has been obtained, if the bottle, with the accompanying slip filled out, is left at any one of these stations, it will be collected by the Department, examined microscopically, and a report of the examination forwarded to the attending physician free of charge. The blank accompanying the sample should be fully filled out in every case.

Health Reports.—The following statistics concerning smallpox, yellow fever, cholera, and plague, have been received in the office of the supervising surgeon-general of the U. S. Marine Hospital Service, during the week ending June 26, 1897:

SMALLPOX, UNITED STATES.			
		Cases.	Deaths.

The Recent Smallpox Outbreak in Chicago.—One death from smallpox—that of a woman who had never been vaccinated—occurred in Chicago last month. Notwithstanding the fact that hundreds of persons were exposed to the disease during the highly contagious stage, only six contracted it. This would seem to illustrate the almost perfect vaccinal protection of the population of Chicago and the importance of maintaining the present system of continuous, unremitting vaccination. The work of Chief Medical Inspector Garrott and his corps of vaccinators should also be mentioned. Every person within a radius of several blocks of each infected house was immediately vaccinated or revaccinated; nearly 5,000 packing-house employees were similarly treated as a result of one case which occurred in the packing-house district, as well as the crews of trains running south into Texas and the Gulf States, the first case having been that of a cook on a dining-car which arrived in Chicago from the City of Mexico. Dr. Garrott employs the glycerinated vaccine lymph, not alone for prophylactic purposes, but because it has a modifying effect on the character of the disease if the latter develops. He has also adopted the practice of daily vaccinations until “it takes”—instead of every second or third day—and expects modifying effects even after seven-days’ exposure. Fluid lymph was adopted by the department in August, 1895, after a systematic bacteriologic and clinical examination of all samples of vaccine then in use. It is an emulsion of vaccine lymph in glycerin, stored in sealed glass tubes, each tube containing material for one vaccination. Its use is followed by typical results with a diminution of the usual inflammatory vaccine vesicle, less constitutional disturbance, and freedom from suppurating sores, inflamed glands and lymph vessels.

OBITUARY RESOLUTIONS.

RESOLUTIONS BY THE FACULTY OF BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE faculty of the Bellevue Hospital Medical College have the painful duty of directing a formal record in their minutes of the untimely and sudden death of their beloved colleague and president, the late Professor William Thomson Lusk, on June 12, 1897. Dr. Lusk was an alumnus of the College, the class of 1864, and class valedictorian. He became one of the instructors in the summer session in 1870. He was appointed professor of obstetrics in 1871 and president of the faculty in 1889. His great ability as a teacher and voluminous writer commanded the respect and admiration of the profession at home and abroad. His public services in the institutions under the charge of the Commissioners of Public Charities were rewarded by the appreciation and gratitude of all interested in medical charities. His devoted work in behalf of medical education connected his name most prominently with the teaching of medicine, and especially with the Bellevue Hospital Medical College. But above all, his fearless honesty of purpose and his exquisite gentleness of character and manner so endeared him to his associates in the College, that we, his loving colleagues

and friends, feel, in his death, a personal bereavement which words fail adequately to express. In common with his family, the profession, and his many devoted friends, we mourn his loss and deplore the premature end of a most useful and valuable life.

AUSTIN FLINT,
Secretary.

RESOLUTIONS BY THE MEDICAL BOARD OF ST. VINCENT'S HOSPITAL.

At a meeting of the Medical Board of St. Vincent's Hospital, held June 14, 1897, to take action on the death of Dr. William T. Lusk,

IT WAS RESOLVED to give expression of the deep sorrow of the members of the Board at the death of one who had labored so long and so well for the institution and for its inmates, and of a colleague who, by his courtesy and geniality, had won the high esteem of his associates.

IT WAS FURTHER RESOLVED to express to the family of the deceased the condolence of the members of the Board, and to forward a copy of this action to the medical journals.

CORRESPONDENCE.

THYROID EXTRACT IN THE TREATMENT OF FIBROID TUMORS OF THE UTERUS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I venture to ask the attention of the profession to the efficacy of thyroid extract in the treatment of fibroid tumors. I refer more particularly to fibroid tumors of the uterus. We are all familiar with the beneficent action of the remedy in the metrorrhagias of that condition (an action common, it appears, to hemorrhage due to similar states of the endometrium in other affections), but perhaps less so with the effects upon the growth itself. In this connection I hope soon to publish in your estimable journal a detailed report of several cases in which, to me, remarkable results have been obtained. In each case not only has growth been checked, but there has been a decided retrocession, accompanied by marked amelioration of local symptoms and improvement in general health.

I know of no remedy which meets all the indications in this disorder so markedly as thyroid extract. It should be given in much the same manner and with about the same limitations as in myxedema; its effect upon cardiac action and arterial tension being closely watched.

Respectfully yours,
NEW YORK, June 23, 1897.

W. M. POLK.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE PENNSYLVANIA EPILEPTIC HOSPITAL AND COLONY FARM—PHILADELPHIA COUNTY MEDICAL SOCIETY—PATHOLOGICAL SOCIETY OF PHILADELPHIA.

PHILADELPHIA, June 26, 1897.

IN view of the fact that Pennsylvania possesses no institution for the treatment of epileptics, of whom there are at least ten thousand within the borders of the State, the

growth of the project for the establishment of an epileptic hospital conducted on the village-community system by the Pennsylvania Epileptic Hospital and Colony Farm is being watched with no little interest by those concerned in the better treatment of this class of unfortunate patients.

The new institution, for the construction of which active steps have already been taken, is situated at Oakburne, a beautiful suburb within easy reach of this city, and here the incorporators are establishing an institution which bids fair to become a model of its kind, and which will make possible the employment of the very best modes of treatment for a class of people which, under other circumstances, must needs be more or less proscribed and neglected. Patients will here be placed under the most favorable circumstances of a continuous outdoor life, congenial occupation will be furnished them, and they will be relieved from the consciousness that they are looked upon as pariahs of society—a most important thing to be considered in the betterment of their condition. The Oakburne institution will not limit its work in any local sense of the word, but, in event of its adequate recognition in State appropriations, proposes to receive patients from every county in the State, for many of whom at present the almshouse or the insane asylum is the only refuge. In the present universal and indiscriminate clamor for State funds for hospital maintenance everywhere, and the claims of "pressing need" by some hospitals which could, upon close investigation, present but flimsy excuses for their existence, it is to be sincerely hoped that the Pennsylvania Epileptic Hospital and Colony Farm will receive the aid it merits in carrying on a valuable and eminently charitable work.

At the last stated meeting of the Philadelphia County Medical Society, held on June 23d, Dr. A. G. Thomson reported a case of "Complete Blindness Due to an Acute Poisoning from Over-use of Jamaica Ginger; Recovery Followed by Toxic Amblyopia of Ordinary Chronic Form." The subject of the poisoning, after the ingestion of more than a quart of Jamaica ginger, taken in lieu of an alcoholic beverage, suddenly became completely blind, and remained in this condition for a period of seven days, when his sight became gradually restored, although evidences of a toxic amblyopia persisted. Dr. Thomson lucidly explained the pathology of the lesion, and illustrated his remarks by eye-ground charts of the case in question. In the discussion of the paper, Dr. G. E. de Schweinitz spoke at length of toxic amblyopias in general, and expressed his belief that in amblyopias due to the use of alcohol, the poorer the grade of stimulant, the worse the amblyopia produced; in reference to tobacco amblyopias, of which he particularly spoke, Dr. de Schweinitz questioned if auto-intoxication did not play an important rôle as a casual agent of the condition, inasmuch as in such cases he had noticed that the eye symptoms were preceded by signs of the intoxication elsewhere. The whole subject was further elaborated by the views of Dr. Edward Jackson, Dr. A. A. Eshner, and others who participated in the discussion.

Dr. A. A. Eshner read a very interesting paper on "Hysteria in Early Life," which included seven cases of

this condition coming under the observation of the speaker. His remarks pertained to the coexistence in children of hysteria and epilepsy, to the difficulties surrounding the diagnosis of such cases, many of which it was obviously impossible to definitely class as one or the other condition, and to the importance of the recognition by the profession of hysteria in early life. Much light was thrown on this uncommon disease by the contribution of Dr. Eshner and by the discussion of the paper by Drs. C. W. Burr and G. E. de Schweinitz.

Dr. Henry Beates, Jr., read a communication, entitled "Remarks on Some of the Causes Defeating the Proper Progress of Therapeutics." He took up for consideration the poor results accruing from the modern treatment of disease, and took occasion to point out some of the causes for these unsatisfactory evidences of therapeutic advance.

At the last stated meeting of the Pathological Society of Philadelphia, held on June 24th, Drs. Swan and Ohnesorg exhibited a specimen of aortic aneurism which arose from behind the origin of the innominate artery, and weighed 1080 grams; the heart was hypertrophied, and there was considerable erosion of the sternum from the pressure of the aneurism. Dr. W. G. Spiller showed a number of stained specimens of the nerve-cells of the brain, and gave an interesting *résumé* of their histologic peculiarities and the methods by which the motor and sensory cells may be distinguished. Dr. C. W. Burr exhibited a tumor of the brain which occurred in a case which was considered clinically as one of mastoid disease, with a profuse purulent discharge from the ear. An operation for the mastoid condition failed to give relief, and upon *post-mortem* examination a massive growth, probably a gumma, was found in the anterior portion of the left hemisphere. Dr. Burr drew particular attention to the existence of such growths in patients suffering from mastoid disease, and referred to a similar case coming under his observation some years ago, in which it was impossible to make an *ante-mortem* diagnosis of brain tumor.

Among the physicians of this city who have recently sailed for Europe may be mentioned Drs. J. William White and W. Easterly Ashton, who left on June 19th, and Drs. Judson Deland and Robert N. Kelly, both of whom sailed on June 26th to attend the International Medical Congress at Moscow. Dr. P. S. Donnellan intends sailing within the next week, and will spend the summer in the British Isles.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE VIENNA POLYCLINIC CELEBRATES ITS 25TH ANNIVERSARY—THE WIDAL REACTION AND ITS GENERAL ACCEPTANCE—SPECIFIC PRECIPITATES BY SERUMS IN FILTERED CULTURES OF TYPHOID AND CHOLERA BACILLI—THE ROLE OF AMEBÆ IN DYSENTERY—TWO INTERESTING CASES OF MAJOR HYSTERIA—INTEREST IN THE MOSCOW CONGRESS AND SOME RECENTLY ANNOUNCED ARRANGEMENTS.

VIENNA, June 5, 1897.

ON May 11th the Vienna Polyclinic celebrated the 25th anniversary of its foundation. Its development and

present status are of special interest, as it was, I believe, the first of the Polyclinics which arranged its courses for special teaching and is the model on which others have been founded. Many American medical students of twenty years ago or even less must remember it in its old quarters when a great many inconveniences and hindrances to satisfactory work were encountered, which the present magnificent hospital building and well-arranged, well-lighted clinic rooms have obviated. The appreciation of its advantages may be best judged from the number of its students, 869 having registered last year.

Two things seem of interest in the Polyclinic hospital report for 1896. The income in round numbers was 43,000 gulden (about \$17,500), and the expenditures 38,200 gulden (\$15,500). Surpluses in hospital finance are rare enough to deserve notice. With the expenditure of \$15,500 some 53,000 out-patients and 1200 in-patients were cared for. A much smaller outlay than would be required under corresponding circumstances in America.

It is very evident that the medical world at present is in an attitude of ready expectancy with regard to new discoveries or new applications of scientific principles which promise to be of diagnostic or therapeutic importance. The Röntgen-rays, though so recently discovered, have been very thoroughly exploited everywhere and hardly a country has failed to add its mite of some application of them in special circumstances of importance to medicine or surgery. Widal's agglutinative reaction in typhoid has been scarcely a year before the profession, and from all sides come important series of observations on its diagnostic value. All are agreed that it is a decided aid in diagnosis, though the impression generally conveyed is that it is not of such absolutely facile pathognomonic significance as was at first hoped. The conclusion seems to be gradually gaining ground that the reaction produced is not absolutely specific and that the effect is rather a quantitative than a qualitative one. Undiluted or only slightly diluted typhoid serum will produce an agglutinative reaction with certain other microbic cultures, notably of the bacillus coli communis. On the other hand, certain normal serums, when undiluted, produce an agglutinative reaction, even with typhoid cultures, which is extremely difficult if not impossible to distinguish from that produced by typhoid serum.

Some of the developments in the matter of agglutinative reactions with other serums promise interesting results. For instance, the German government plague commission in India reports that a very similar reaction takes place in cultures of the plague bacillus when the serum of persons who have had plague, or of animals which have been inoculated with the disease and have recovered, is mixed with the cultures.

Dr. Kraus, at a meeting of the Royal Imperial Medical Society of Vienna, on April 30th, gave a preliminary report of some observations made with filtered cultures of typhoid and cholera bacilli. With absolutely germ-free cultures certain changes which are specific for each serum and culture may be noticed. Typhoid serum will produce a precipitate in filtered typhoid cultures more or

less plentiful according to the concentration of the serum and the age of the culture, and the same occurs for cholera products. Similar appearances are not produced when any but the specific allied serum is added to the filtered culture.

The precipitate in each case seems to contain an alkali albumin and a peptone, and Kraus is of the opinion that they are the result of certain secretions of the bacteria precipitated by specific properties of the serums. He suggests that further study along these lines may help to elucidate the vexed question as to whether immunity is due to chemic properties in the serum, or to vital properties of the morphologic elements of the blood. The subject is of paramount importance for a proper understanding of immunity and of very practical usefulness in the study of immunization. It is just now a much mooted point between the French and German schools of bacteriology, and has called forth some very interesting work from great leaders of the two schools, Metchnikoff and Pfeiffer.

A recent communication from Professor Schrötter's clinic at the Vienna General Hospital throws more doubt on the subject of the specific etiologic action of amebæ in dysentery. These observations, the result of some experiments on cats, are contradictory of the preliminary report of a case of dysentery in which a special form of ameba was found in the stools and was considered to be the etiologic factor in the affection. Animals injected with the stools acquired dysenteric symptoms and the amebæ appeared in the stools. After the disappearance of the germ, however, the dysenteric stools continued, and the injection of some of this material into another animal set up similar symptoms. No amebæ could be found in the dejections of the second animal at any time, though they were characteristically dysenteric.

The autopsies showed similar lesions in both animals. Curiously enough, these were not confined to and were not even most marked in the large intestine. The mucous membrane in the neighborhood of the ileocecal valve in the small intestine and for some distance beyond it was the seat of the ulcerative lesions characteristic of the disease, while the large intestine was only slightly affected.

The reporter calls special attention to it in view of the highly lauded, much-used local treatment which is so common, and which would be of absolutely no avail with lesions situated as these were. He suggests the existence, at least in non-tropical forms, of dysentery where amebæ are found of some other etiologic element, probably a coincident bacterium, as the true cause of the disease.

Two interesting cases of major hysteria have been reported from Vienna hospitals recently. One of them serves to show what pranks the functional neuroses may play even with the refinements of modern scientific diagnostic methods. The patient, a female of twenty, developed gastric symptoms, the main features of which were pain after eating, localized in the stomach region, and the vomiting of blood. An examination of the stomach contents showed the presence of free hydrochloric

acid considerably in excess of normal, and a preliminary diagnosis of gastric ulcer was made. After a month of the usual treatment for the condition there was marked amelioration of symptoms, though the patient had lost in the meantime considerable weight. A second examination of the stomach contents made at this time showed the absence of free hydrochloric acid, a great diminution in the combined hydrochloric, and the presence of a notable amount of lactic acid. The diagnosis of carcinoma, however, was not made, as the age of the patient made it so improbable and certain suspicious neurotic symptoms had in the meantime been noted. Verily, the neuroses do not lose in interest as time goes on.

The second case was one of the rarer instance of bleeding without known cause from a number of peripheral capillaries. Besides hemorrhage from mucous membranes there occurred bleeding from the mammae (of which not more than half a dozen cases have been reported), and bleeding from various skin areas, especially from the webs of the fingers.

The recent announcements by the committee of arrangements for the International Medical Congress at Moscow of the opportunities which will be afforded visiting physicians to see various places of medical and scientific interest in the Empire has awakened new interest very generally in the Congress. The trip to the Caucasus and its health resorts, with side trips on the Black and Caspian seas, the journey to last fifteen days, may be taken for merely a nominal sum (about \$28). The distance is some 2000 miles through the heart of Russia, and the sleeping cars are to be always at the disposal of the travelers, so that there will be no additional expense for lodging. The railway rates in Russia itself for accredited visitors to the Congress have not yet been definitely announced. There is even more of red tape it seems in the matter of governmental railways than our own, but it is now known for certain that there will be notable reductions in the already extremely low fares.

CAUSE OF ACUTE EDEMA OF THE LUNG—TREATMENT OF LOCOMOTOR ATAXIA BY ELONGATION OF THE SPINAL CORD—TWO CASES OF PERFORATION OF THE STOMACH—AN ANATOMIC STUDY OF THE REDRESSEMENT BRUSQUE OF CALOT—RECOVERY FROM GANGRENOUS PLEURISY—A TEST FOR THE PERMEABILITY OF THE KIDNEY—TREATMENT OF RHEUMATISM BY COMPRESSES SATURATED WITH SALICYLATE OF METHYL—A CASE OF ACUTE STREPTOCOCCIC MACROGLOSSIA.

AT the session of the Academy of Medicine held April 27th, HUCHARD discussed the subject of *acute edema of the lung*, the cause of which has never been thoroughly understood. In his opinion the sequence of pathologic processes is as follows: First, a peri-aortitis produces a disturbance of the innervation of the heart and lungs; second, there is a considerable increase of the vascular tension in the pulmonary circulation; third, there is a rapid insufficiency of the right ventricle.

In accordance with these causes the medicinal treatment should be to reduce the work of the heart. This is best accomplished by the withdrawal of ten or twelve ounces of blood from a vein and by wet or dry cups applied to the thoracic and hepatic regions. The cardiac collapse is best met by injections of caffeine and camphorated oil. For the disturbance of innervation and the parietic state of the bronchi and diaphragm, hypodermic injections of strychnin and cauterization of the sternal region are advisable. Diuresis should be as free as possible. An exclusively milk diet and from twenty to forty grains of theobromin per day will accomplish this result.

A paper by CHIPAULT was read upon *the treatment of locomotor ataxia by elongation of the spinal cord*. This elongation is obtained not by suspension of the patient but by flexion of the vertebral column. Of forty-seven patients in the second stage of the disease treated by this method, twenty-two, or almost one-half, were relieved of all their symptoms, fifteen others were somewhat benefited, while the remaining ten received no benefit. The number of *séances* of flexion was in no case less than fifteen or twenty. They took place every two days and lasted from five to eight minutes.

At the session of March 4th DENTU reported *two cases of perforation of the stomach*, in one of which there were two openings and the patient died some hours after operation. In the other, operation was performed twenty-six hours after the perforation made itself manifest. There was a single perforation in the vicinity of the pylorus surrounded by fibrinous membranes, and as suture was impossible the site of perforation was tamponed and drained. The patient recovered. In both of these cases the cardinal signs of diagnosis, namely, excruciating pain in the pit of the stomach and disappearance of liver dulness, were both observed.

At the session of May 11, MENARD described the *results produced upon five cadavers presenting the deformity of Pott's disease by redressement brusque*, a method of treatment recently described by Calot. As a result of this forcible reduction of the deformity the bodies of vertebrae were separated a distance of one, two, or even three inches. The meninges and the cord did not appear to suffer in any way. In every case in which there was an anterior or lateral tuberculous abscess it was torn open and the tuberculous material brought into direct contact with the pleura or the meninges.

An anatomic study of cured cases of Pott's disease seems to indicate that at no period of the affection, not even in those cases in which a cure is obtained, is there new formation of osseous tissue. In a word, tuberculosis destroys the osseous tissue of the vertebral column but does not reproduce it. One is forced to the conclusion, therefore, that the interval between the bones, in patients subjected to Calot's treatment, are not filled in with an osseous callous and that the deformity is bound to recur.

COMBY and VOGT presented to the Medical Society of the Hospitals on April 30, a boy, aged eleven years, upon whom they had performed pleurotomy under discouraging circumstances. The illness began with an effusion in the left pleural cavity accompanied by unusually severe

symptoms of a typhoid character. On the third day pneumothorax developed. On the ninth day fetid pus, with a gangrenous odor, was obtained by aspiration. In the view of the almost fatal prognosis without intervention the pleural cavity was opened and irrigated with warm boracic-acid solution until the fluid returned perfectly clear. The pleura was gangrenous. The pleural cavity was irrigated daily with permanganate of potassium solution 1 to 2000. The case is interesting as showing the possibility of recovery after operation from a desperate condition. Examination of the pus showed that it contained the streptothrix funiculi, which was considered to be the cause not of the empyema but of its putridity.

ACHARD and CASTAIGNE described the significance of a test for determining the permeability of the kidney. Four grains of methyl blue dissolved in water are injected subcutaneously and the patient immediately passes water. Micturition is repeated at stated intervals, say every half hour, or hour. A simple inspection of the urine usually suffices to determine the presence of methyl blue, or the color may be collected by a few drops of chloroform added to the urine and shaken up with it in a test tube. The normal kidney gives a faint trace of blue in the urine in a half hour, and the reaction is very well marked inside of an hour. It reaches its maximum in from three to four hours, and disappears in from 1½ to two days. In patients whose kidneys are affected the appearance of the blue is delayed until after the first hour or perhaps later, or in some cases it does not appear at all. In twenty-two cases verified by autopsy this test has never failed, and in seventy-seven cases in which it was applied it failed in only four cases to agree with the clinical symptoms. This test seems likely to be of value in cases of Bright's disease without albuminuria, and also in cases of albuminuria without nephritis. It reveals the latent nephritis of tuberculous kidney, as was verified seven times at autopsy.

At the session of May 7th, LEMOINE stated that he had treated nine *rheumatic patients with compresses saturated with salicylate of methyl* and found that relief obtained was more rapid than that obtained by internal treatment with salicylate of soda. Essence of wintergreen, which contains ninety per cent. of the methyl salt, is poured upon a compress. This is placed upon the joint and covered with oiled silk or gutta-percha tissue, and held in place by a bandage. Two or three drams may be used in this manner without producing vertigo or any unpleasant symptoms.

SIDNEY found this treatment more efficacious than that of salicylate of soda taken internally in cases of subacute and chronic rheumatism. He employs the drug in much smaller quantities than Lemoine, putting only twenty-five or thirty drops upon the compress. One patient with gouty arthritis suffered from headaches and ringing in the ears after the application of a compress containing fifty drops.

MARIE reported that a diabetic patient excreting daily over an ounce of sugar was given methyl blue in doses varying from ten to twenty grains per day. In fifteen days the sugar had entirely disappeared from the urine.

At the session of the Biological Society held May 1st, LINOSSIER called attention to the fact that *pancreatic digestion is stopped by contact for a few seconds with abnormally acid gastric juice*. This result does not follow in all patients with hyperacidity, because the contents of the stomach as they pass into the intestine may be neutralized by the bile. It is most likely to occur in patients in whom hyperacidity is combined with hypersecretion. This explains the emaciated and cachectic appearance of these persons when contrasted with others in whom gastric digestion is absolutely wanting, but in whom intestinal digestion is undisturbed. The therapeutic suggestion is to prescribe alkalis toward the end of digestion, thus not only relieving the pains in the stomach, but also protecting the pancreatic digestion.

SABRAZES and BOUSQUET described a case of *acute streptococcic macroglossia* at the Society of Dermatology and Syphilis at the meeting held April 26th. The patient, a primipara, aged thirty-nine, a victim of tuberculosis and syphilis, aborted at the fifth month. She suffered from chills, fever, nausea, and albuminuria, and two days after the abortion the uterus was curetted. A bronchopneumonia and a subacute inflammation of the metacarpal phalangeal joint of the right index finger followed. One week after the abortion the tongue became greatly swollen, protruding from the month. There also was swelling of the throat, and dyspnea. The patient died of cardiac failure on the tenth day of her illness. The autopsy showed nodules of bronchopneumonia, a tricuspid endocarditis, a double serofibrinous pleurisy with effusion, large white kidneys, and a marked glossitis, especially of the anterior portion of the tongue, which was three times its normal volume. The inflammatory and degenerative alterations in its substance were produced by streptococci which existed there in great numbers.

Vienna.

A CASE OF UNUSUAL EXTENSIVE NEVUS PILOSIS—WHY RENAL CALCULI ARE SEEN WITH DIFFICULTY WITH THE X-RAY.

In the session of the Imperio-Royal Society of Physicians held April 30th, HEBRA showed a case of *unusually extensive nevus piloris*, occupying the left side of the face, the front of the body, and a portion of the extremities of a six-year-old girl. The mother and the sisters of this child were unusually hairy, and the nevus in her was covered with hairs, especially in those portions of the body where hairs grow in men but not in women. The interesting feature in this case is that this nevus was not congenital, but at birth the parts where it now exists were raw and bled easily. Two weeks later, when they were completely covered with epithelium, there appeared here and there dark spots, and in three-months' time the nevus had reached the dimensions which it afterward maintained. The development of this nevus a short time after birth is perhaps to be compared with the fact attested by numerous observers that the children of certain races of negroes are born with a light skin, while others are already black at birth.

FRISCH attempted to find out *why renal calculi*, even

those which are large enough to be palpable, *are seen with difficulty with the X-ray*. He found that stones composed of urates, and also those composed of ammonio-magnesium phosphate, offer little obstruction to the rays and therefore appear pale. Oxalic calculi throw the deepest shadow, while amorphous phosphates show fairly well. It is sometimes possible to make out the different layers of the stone. Thus one which was composed externally of phosphates, and was smooth and round, was seen by means of the ray to contain a rough core of calcic oxalate.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE, SECTION ON OPHTHALMOLOGY AND OTOTOLOGY.

Stated Meeting, Held Monday, April 19, 1897.

The President, DR. EMIL GRUENING, in the Chair.
DR. HERMAN KNAPP presented a case of

LUPUS OF THE LACHRYMAL SAC AND CONJUNCTIVA OF BOTH EYES.

The patient was a colored girl about fifteen years of age, in whom the condition was well marked. The disease had begun in the nose and infected the eyes through the lachrymal canals. The skin eruption presented the typical picture of lupus. The treatment proposed was destruction of the diseased tissues by the galvanocautery.

DR. R. DENIG exhibited specimens illustrating

THE CHANGES OCCURRING IN COMMOTIO RETINÆ.

The speaker had observed in experimental work on rabbits the ophthalmoscopic picture of subchoroidal hemorrhage, and had found it quite different from that of the so-called *commotio retinae*. In the former a grayish-white discoloration, which has the appearance of being in the deeper layers of the retina, is observed, while in *commotio retinae* the discoloration is milky-white and seems to be upon the surface of the retina. The anatomic conditions, therefore, do not consist of subchoroidal hemorrhage and edema retinae, but present typical changes in the nerve-fiber layer of the retina as follows: Corresponding to the ophthalmoscopic picture, there are many small elevations in the nerve-fiber layer of the retina strung together like pearls, with depressions between. The elevations are covered by *membrana limitans*, and the latter is torn in pieces. The ganglionic cells are here displaced somewhat backward. The nerve-fiber layer between the elevations is slightly thickened. Under a powerful magnifying glass the elevations have the appearance of a mushroom, with irregularly formed openings of various sizes.

The other layers of the retina are normal, and contain between the rods and cones some spheroid structures as exudations of the vessels of the choroid; the latter, immediately after the blow, being contracted for about thirty seconds, become paralyzed and dilated with simultaneous hyperemia of the optic disc. This condition could be very well observed in albinotic rabbits. Subchoroidal hemorrhages are caused only by very severe blows, and do not appear by lesser violence. If one may draw parallel

inferences from the rabbit's eye and that of the human being, it can easily be understood why in some instances of *commotio retinae* there exists, in spite of a normal fundus, a diminution of the peripheral and central vision in the form of *scoloma* or decrease of sight.

These changes are explained as follows: On receiving the blow the vitreous is forced against the retina like a wave, rebounding with the same violence against the starting point. Through the violence of this wave the stigmata of Mullers fibers are distended, at some spots the *limitans* is torn apart, and the vitreous fluid is pressed into the nerve-fiber layer of the retina. The latter becomes disentangled, giving rise to the above microscopic picture and, if large enough, producing the ophthalmoscopic picture of milky discoloration of the retina. The vitreous liquid, pressed inward, becomes gradually absorbed, the disentangled nerve-fibers join together, and all structures return to the normal. The fact that no harm is done to the nerve-fibers may be explained by the well-known resistance of the axis cylinders, for instance, in multiple sclerosis.

A paper, entitled

TRAUMATIC PROLAPSE OF THE IRIS AND ITS TREATMENT,

was read by DR. G. A. DESCHWEINITZ of Philadelphia. (See page 8.)

DISCUSSION.

DR. CHARLES J. KIPP of Newark, N. J., agreed in the main with the author. He was in the habit of abscising practically every prolapsed iris seen within a few days after the injury, and some that have been prolapsed for a longer period. When the rupture is situated near the sclerocorneal junction, he sometimes introduces a stitch to hold the wound together, and has never seen unpleasant results follow this procedure.

DR. T. R. POOLEY thought the position taken by the author, while admirable in some respects, was nevertheless open to criticism. Surgery of the eye does not differ from surgery elsewhere, and one of the first and fundamental rules of surgery, where a wound is concerned, is to protect it from any foreign body and to bring the edges of that wound together, and maintain them there. To do this, it may or may not be necessary to introduce sutures. They are seldom required in wounds of the eye, but the first and most important thing is to remove the foreign body. The iris here is a foreign body, and the proper treatment is abscission in all cases, except where there is an infectious disease of the eye, otherwise the iris will heal in the scar and the eye be subjected to traction and recurring attacks of iritis, and, possibly, glaucoma. Abscission is easily done when the wound is recent, but becomes a somewhat difficult matter if the condition has lasted some time. The author had stated that wounds of the conjunctiva are not apt to become infected, and in a recent paper Dr. Knapp said he rarely, or never, saw sympathetic ophthalmia follow prolapse of the iris, unless the latter was wounded by the injury or by the surgeon. The speaker's experience showed that conjunctival wounds are very liable to infection.

DR. P. A. CALLAN said that, as he grew older, he became more conservative. Whenever he saw a recent case of prolapse of the iris he put the patient to bed, applied ice-cold compresses and a firm bandage, employed mydriatics and waited three or four days to see what the result would be. If at the end of this time nothing was gained, he abscised the iris. He had seen brilliant results follow this treatment. He did not, however, believe in the expectant treatment when carried so far as to keep a patient in bed fifty-four days, as was done in Dr. Knapp's case.

DR. J. E. WEEKS said the stand he took was not quite so radical as that of Dr. Pooley, nor quite so conservative as that of Dr. de Schweinitz and Dr. Knapp. He thought the condition referred to by the author was incarceration, rather than prolapse of the iris. When this occurs there is present beneath the lids an elevation which is constantly being rubbed against by movements of the eye and eyelids, and there necessarily results more or less irritation. Prolapse of the iris may also be the means of carrying the secretion of an infectious disease of the lachrymal sac to the interior of the eye. It was his practice to abscise when the case is seen in the early stage and also in later stages whenever it is possible, provided a firm cicatrix has not formed. The plastic exudate which covers the iris after rupture of the cornea can easily be removed and the wound made perfectly clean. Healing can be obtained by reposition of what remains of the iris; if this is not possible, the iris should be excised. Little or no danger of infecting the eye is incurred. The results of conservative treatment are not good and the process of repair is much prolonged, whereas rapid recovery and no damage to the eyeball follow more energetic treatment.

DR. DAVID WEBSTER said he had not seen many cases of traumatic prolapse of the iris, except as a result of cataract operation. In such cases he followed one of the three plans mapped out by the author, *i.e.*, abscission of the prolapsed iris, reposition, or conservative treatment. He had often replaced a prolapsed iris, but had never been able to maintain it in position. At one time he had treated these cases by cauterization, but had abandoned the treatment. With regard to incarceration of the iris, he thought the treatment should be conservative.

DR. W. F. MITTENDORF was of the opinion that immediate abscission is the proper treatment of this condition, and at times he had performed the operation late at night.

DR. HERMAN KNAPP was in favor of non-operative treatment. In some cases he would abscise a prolapsed iris if he could make a clean iridectomy. He had been led to follow the conservative plan of treatment by the good results obtained twenty years ago in cases of prolapse of the iris when nothing was done for them. He never operated in those cases where the iris was not lacerated, nor the deeper parts injured, and where there was a chance of a linear scar resulting. What Dr. Pooley had said in regard to a prolapsed iris being a foreign body is true, but in this condition the iris protects the deeper parts of the eye by plugging up the external opening and thus preventing the entrance of germs. Regarding the reduction of a prolapsed iris, he thought this a very un-

certain method and no longer attempted it. Prolapse of the ciliary border of the eye after cataract operation is a most unfortunate complication, as it produces much swelling and a very unpleasant form of astigmatism.

The CHAIRMAN said that, as many wounds of the cornea which permit of prolapse of the iris are made with a pointed instrument, it is very difficult to abscise the iris properly through such a small wound, especially when the case is seen some time after the injury. Under such circumstances the wound should be enlarged.

DR. DE SCHWEINITZ, in closing, said he feared he had not made himself clear, for he was not so conservative in his views as Dr. Pooley seemed to think. He made it a rule to abscise in all cases, except in those where the wound reached across the entire cornea. In such cases the iris acts as a bar to the entrance of germs into the eye, and these he treated expectantly. Dr. Knapp had covered the ground when he said we should excise whenever a clean iridectomy could be done.

GERMAN SURGICAL SOCIETY.

Meeting Held at Langenbeck Haus, Berlin, April 21 to 24, 1897.

[From our Special Correspondent.]

The President, PROFESSOR BRUNS of Tübingen, in the Chair.

SURGICAL TREATMENT OF GASTRIC ULCER.

PROFESSOR V. LUBE of Würzburg reported that he had treated 1000 cases of gastric ulcer medicinally during the past ten years, the treatment consisting of rest in bed, hot applications, the administration of Carlsbad water, and a carefully regulated diet. Seventy-four per cent. of the patients were cured, 21 per cent. were improved, 16 per cent. were not improved, 4 per cent. lost sight of before the course of treatment was completed, and 2.4 per cent. died. He laid down the indications for surgical interference as follows: (1) Profuse, repeated bleeding, (2) severe and continued pain and vomiting, (3) perigastritis, with adhesions and abscess, (4) perforation.

PROFESSOR MICULICZ of Breslau read a paper on

METHODS OF OPERATING IN GASTRIC ULCER, AND INDICATIONS FOR OPERATION.

He said that 238 cases of operation for gastric ulcer had been reported, with a mortality of ten per cent. He has operated on thirty-six patients presenting this lesion. He expressed it as his opinion that resection is the most dangerous operation, and that in all cases but those having cancer, or ulcer of the anterior wall, a pyloroplasty operation is to be preferred. In instances of perforation, operative measures should be instituted at the earliest possible moment, as delay increases the danger of peritoneal infection. The infiltration method of anesthesia under these circumstances is often preferable to the use of ether or chloroform. It is frequently necessary to make use of the actual cautery in order to arrest the hemorrhage. He approved of the indications for operation as presented by v. Leube, and reported a series of cases in which patients

had remained perfectly well from seven to ten years subsequent to operation.

THE SURGICAL TREATMENT OF DIFFUSE PERITONITIS was the subject of a paper by DR. KROTE of Berlin. He said that the objects to be attained by operation are to prevent further infection and to relieve intraperitoneal pressure by removing the exudate, thus allowing of peristalsis, free circulation, and easy respiration. He recommended early operation, flushing of the cavity with sterile water, packing with gauze, and drainage. Sixty-eight cases were reported, with twenty-two recoveries.

DR. MARWEDEL of Heidelberg reported

A CLINICAL EXPERIENCE WITH THE USE OF THE MURPHY BUTTON.

He said that since the last medical congress fifty-five patients have been operated upon, and the Murphy button used, in Czerny's clinic. In thirty-five cases the anastomosis was between the stomach and intestine, in three it was between the gall-bladder and intestine, and in the remainder it was intestinal. Twenty-nine of the patients had a carcinomatous stenosis. Favorable result in several instances was attributed to the short time occupied in performing the operation.

The average time at which the button was passed was twelve days, the earliest being eight days and the latest forty-five. Of 328 cases thus far reported, stricture of the intestine has occurred in but three. The speaker drew attention to the inferior quality of the Murphy buttons frequently offered for sale, and insisted upon the necessity of selecting a reliable one when about to perform an anastomosis.

DR. KUMMEL of Hamburg read a paper on

THE SIGNIFICANCE OF THE ROENTGEN RAY IN SURGERY.

In addition to the ordinary uses of the ray in locating the presence of foreign metallic bodies in the body, the author had employed it in the diagnosis of stone in the bladder and kidney, of gall-stones, in fractures and dislocations, and in syphilitic, tuberculous, and osteomyelitic changes in bone, etc. He illustrated the points of his paper by showing more than one hundred finely executed plates.

During the discussion, DR. HOFFA of Würzburg spoke at some length, and showed numerous plates illustrating the use of the ray in the recognition and correction of deformities.

THE OPERATIVE TREATMENT OF HIGH STRICTURE OF THE RECTUM

was the title of a paper read by PROFESSOR SONNENBURG of Berlin. In syphilitic and gonorrheal stricture, his method of procedure is to resect the coccyx and a portion of the sacrum, lay open the stricture, and tampon the wound for several months. His first patient operated upon in this way six years ago has remained in good condition since. In cases of cancer located high in the rectum and in the sigmoid flexure, he first frees the growth from its attachments through an abdominal incision. The patient is then placed on his side and the rectum is freed

from below. The sphincter ani is then incised, the gut drawn down and out and divided above the lesion, and the end sewed to the sphincter. In the case of one patient, he removed twenty-two centimeters (seven inches) of intestine in this way. Healing was slow, but the man is now well, fourteen months after the operation.

DR. REHN of Frankfort-on-Main then read a paper on
PENETRATING HEART WOUNDS AND HEART SUTURE.

These wounds, the author said, are seldom met with, and, in consequence, experience in their treatment is slight. Large wounds invariably result in death; small wounds present a possibility of saving life by suitable treatment. It has been demonstrated by *post-mortem* examinations that even complicated wounds may heal.

At the author's request, a series of experiments had been carried out by Dr. Bode of Professor Landois' Physiological Institute, and the fact had been determined that a light touch on the heart of a live rabbit has no effect on the activity of the organ, strong pressure causes arrhythmia, and a puncture causes a short arrest, which is followed by rapid and uneven action. Small wounds have but little tendency to gape, while large wounds, no matter what the direction of the incision, gape widely. Hemorrhage is most severe from auricular wounds, and greater from the right than the left ventricle. Small wounds soon cease to bleed.

The clinical picture in these experiments showed bleeding of variable degree, a rapid, feeble pulse, cyanosis, and marked prostration.

The treatment in cases of slight wounds should be of an expectant order, the patient being kept absolutely quiet. Rehn does not recognize any necessity for venesection, the plan that has been advocated by some. In case operation is decided upon, the left ventricle is accessible after the third and fourth left costal cartilages and a portion of the ribs have been resected. To operate on the auricles, the sternum must be resected.

As an illustration of his method, the author presented a man, aged twenty-two, who had received a stab wound in the fourth left intercostal space on September 7, 1896. Upon admission to the hospital it was found that he was almost pulseless, cyanotic, and that the area of the heart's dulness was increased to the right. The following day he was somewhat better, but the area of dulness had still further increased.

On September 9th the man was much worse, the pulse being small and thread-like, the respirations 76 to the minute, and the heart area of dulness more pronounced. He appeared to be at the point of death. The pleura was incised in the fourth intercostal space, and the fifth costal cartilage and a portion of the rib was excised. The pericardium was laid open, when a wound $1\frac{1}{2}$ cm. long was found in the wall of the right ventricle. There was no loss of blood during systole. Three silk sutures were inserted in the edges of the wound, the clotted blood was washed out from the pericardial sac, and this cavity and the pleura were douched with normal saline solution. The cavities were then packed with iodoform gauze. The patient's pulse and respiration immediately improved, and

he went on to complete recovery, which, however, was complicated by the occurrence of suppurative pleuritis.

DR. BARDENHAUER of Köln reported a case of gunshot wound in which injury of the diaphragm was suspected. The pleura was opened, but no injury was found. The patient died after fourteen days, and at autopsy the bullet was found in the right auricle.

REVIEWS.

THE SURGERY OF THE CHEST. BY STEPHEN PAGET, M.A., Oxon., F.R.C.S., Surgeon to the West London Hospital and to the Metropolitan Hospital. Illustrated. New York: E. B. Treat, 1897.

IT is an uncommon pleasure to read a surgical monograph so well conceived, so well written and so exhaustive as the one under consideration. The author, aside from his own extensive experience in injuries and diseases of the chest, has carefully covered the range of literature bearing on the subject and has carried out the promise made in his preface "to make a collection of such facts and experiences as lie outside the usual course of our work." The fact that this book is the first on the subject to appear in the English language only enhances its present value.

Mr. Paget divides his subject into two parts, the first including injuries, the second diseases of the chest. Passing over the excellent chapter on surgical landmarks and deformities and those on fractures and dislocations, we note that the author commends simple puncture, not aspiration, in cases of pneumothorax due to disease or injury, if the symptoms do not abate under rest and opium. He admits, however, that in certain cases it may be necessary to make a free incision with or without resection of a rib. The prognosis in traumatic hernia of the lung, he regards as good if the lung has not been too long strangulated or is not already infected, and reduction of the hernia seems in most cases to have yielded the most satisfactory results. In cases of hemothorax, rest, next free resection, are advised, although in the latter event preparation for transfusion must be made previously.

The treatment of shock: immobilization of the chest and gauze drainage constitute Paget's advice for wounds of the lung of a penetrating character; but continued hemorrhage demands free exposure with plugging, suturing, or ligaturing of the pulmonary wound. The rare cardiac wounds require rest, possibly resection and opening of the pericardium in case of too great pressure of blood within it. Incision is reserved for urgent cases of primary serous pleural effusion, while aspiration is recommended for the usual cases. Nor does Paget agree in this respect with other authorities, notably in this country, who prefer immediate aspiration to the operation at the end of two or three weeks.

It is in the chapter on "Empyema" that the majority of readers of the book will be most interested, since empyema is the disease most frequently encountered in the chest demanding surgical treatment unless we regard the aspiration of a simple pleural effusion as a surgical oper-

ation. Although there is, in this chapter, not much that is strikingly new, the subject-matter is well arranged and the conclusions will be accepted as those most universally agreed upon. For example, "incision without resection is, at present, out of favor," and "the effusion must not be let out too rapidly" are statements that will meet general approbation. Again, the author condemns irrigation after empyema operations in which, we are sure, he has the sanction of most observant surgeons. In those instances in which the drainage tube becomes lost in the pleural cavity, a not infrequent accident when the tube is not properly secured, a free resection is urged rather than the usually useless tentative measures to recover it.

In speaking of bronchiectasis and its surgical treatment, the author bids the surgeon to be hopeful, giving the encouragement of a long record of successful cases. Each case, he tells us, must be studied on its merits and a different method of procedure followed in each. It was in 1877 that Trousseau laid down the dictum that an abscess of the lung was altogether beyond the reach of surgery and yet a large number of successful cases have been published since that time and similar good results have been chronicled in cases of gangrene of the lung. In "tubercular phthisis," Paget thinks only two conditions are amenable to surgical interference: fetid pyopneumothorax and large tuberculous cavities with septic absorption. Certainly, with the recollection fresh in mind of the romantic suicide of the young Italian surgeon after a fatal attempt to remove the tuberculous apices of his betrothed, surgeons will be skeptical of operation in simple tuberculous infiltration of the apex of the lung.

It is advisable, says the author, to attempt to save a patient's life by operation, when there is obstruction of the air-passages by foreign bodies which are otherwise not removable. Aspiration of the right ventricle may be attempted when this organ is over-distended because of injury. Conservative surgery is advocated in neoplasms of the lung. The chapter on subphrenic abscess is complete and embraces the results of Maydl's extensive studies. In the appendix are given M. Réclus's address at the French Surgical Congress of 1895 and Bulan's treatment of empyema by continuous syphon-drainage.

In this somewhat summary review we have established, we hope, the trustworthiness of the book. The extensive pathology, the judicious selection of casuistic examples, the terse and accurate statements as to the possibilities and limitations of the surgery of the chest, together make up a unique and valuable addition to medical literature. The book is well-printed on good paper and is handsomely illustrated. We have no doubt that we shall see its few imperfections removed in a second edition.

VORLESUNGEN ÜBER ALLGEMEINE PATHOLOGIE. Von DR. M. LÖWIT, o.ö., Professor der allgemeinen und experim. Pathologie aus der k.k. Universität Innsbruck. Erstes Heft: *Die Lehre vom Fieber*. Jena: Gustav Fischer, 1897.

THIS book is a most valuable addition to our knowledge of the various manifestations of fever, and it is one of the most important contributions to general pathology that

has been written for many years. The subject in hand is treated in a most exhaustive manner, quite in keeping with the usual style of the better German writers, and whereas it does not serve as a text-book, still as a work of reference it must be highly commended.

Since bacteriology has been proven to play so important a rôle in pathology, it is not surprising to note that several of the chapters deal with the many and varied effects produced by bacteria on living cells, and their importance in the etiology of fever. That pyrotoxin does not always arise from the bacterial cell-body, but that it is often produced by the metabolism between the organism and the tissues (Brieger) is shown. Some pathogenic bacteria may cause disease and no fever, as in many cases of cholera and tetanus, while some non-pathogenic forms may cause fever alone and no disease.

The various changes occurring in the blood in fever are minutely described and take up a great part of the text. The blood changes are among the most important manifestations of fever, but many problems are wholly unsolved. For instance, the author does not agree with Ughetti, who states that fever does not occur without important and recognizable destructive changes in the blood, and cites for example that ten to twenty-four hours after rabbits are inoculated with anthrax and while their temperature may be from 104° to 106° F. no morphologic or numeric changes can be discovered in the blood.

The book is fully up to date, well stocked with references and well worthy of close study. It is dedicated to Cohnheim's memory.

SYRINGOMYELIA. Alvarenga Prize Essay for the Year 1895. By GUY HINSDALE, M.D. Philadelphia: P. Blakiston & Co.

A NEW CLASSIFICATION OF THE MOTOR ANOMALIES OF THE EYE. Based upon Physiologic Principles, Together with Their Symptoms, Diagnosis, and Treatment. The Prize Essay of the Alumni Association of the College of Physicians and Surgeons, New York, 1896. By ALEXANDER DUANE, M.D. New York: J. H. Vail & Co.

BOTH of these essays have appeared in medical journals, the former in the *International Medical Magazine*, the latter in the *Annals of Ophthalmology and Otology*, and are now reproduced in book form. The former is comprised in 60 pages of text, the latter in 100.

Dr. Hinsdale's contribution is the outcome of a literary task, a review of the literature of syringomyelia, which has, despite the fact that the disease has been generally recognized only during the past decade, already taken on considerable proportions. The only contribution that he makes to the subject is the notes of two cases, duplicates of which can probably be found in almost any large hospital for chronic diseases in the country.

Compared with the opinion on the same subject of Hoffman, of Schlesinger, and of Dimitroff, the brochure before us suffers. It is by no means a complete reflection of the knowledge of the pathogenesis and symptomatology of the disease as to-day established. Careful reading compels the statement that the contributions in the literature

have not been thoroughly digested, nor is the subject matter laid open in the way one has a right to expect in a prize essay.

Dr. Duane's work is deserving of unstinted praise. Carefully planned, well-laid out, with a plain statement of the nature of the problem which he endeavors to solve, the writer attacks the subject in a manner that commands attention from the start and holds it through the many intricacies to the end. When he reaches his conclusion the careful reader is of the author's opinion. From the point of view of literary style alone the essay calls for favorable comment. The subject of motor anomalies of the eye has been so much discussed by certain enthusiasts and faddists during the past few years that an authoritative and scientific essay, such as the contribution of Dr. Duane, is a welcome one.

We would call attention to the erratum on p. 66, sixteenth line from bottom. The word *tenotomy* obviously should read *advancement*.

ARTIFICIAL ANESTHESIA. A. Manual of Anesthetic Agents and Their Employment in the Treatment of Disease. By LAURENCE TURNBULL, M.D., Ph.G., Aural Surgeon to the Jefferson Medical College Hospital, Philadelphia. Fourth edition. Philadelphia: P. Blakiston, Son & Co., 1896.

IN the seven years which have elapsed since the publication of the third edition of Dr. Turnbull's book, many additions have been made to the anesthetic armamentarium, particularly in the field of local anesthesia. These discoveries and the publication of many valuable treatises and articles upon the general subject of anesthesia and upon cognate themes, have rendered this new edition necessary.

The author reaffirms his opinion that ether is the safest general narcotic, but goes too far, we think, when he assigns evil results from its administration to the operator rather than to the agent. Lobular and lobar pneumonias following the skilful use of ether are by no means unknown. We agree with Dr. Turnbull that ether is safer than chloroform as an anesthetic for general use; but in this field above all others, a judicious selection of cases is a powerful factor in obtaining favorable sequels.

We heartily endorse the author's caution that "no one should be allowed to administer any anesthetic without a certain amount of tuition, and no one should receive a diploma until he has shown a knowledge of the chemical composition and physiological action of such anesthetics." It is strange that hospital boards should continue to show indifference to this subject.

All the systemic anesthetics and those with local action are fully considered, with modifications and combinations as they have been suggested by various writers. Indeed, there is no theme connected with anesthesia, general or local, which is not completely discussed.

We wish we could say as much for the literary style of the book as for its contents. The subheadings in the various chapters are in poor taste and give the page a chopped appearance. The diction is not in all parts as clear as it should be. The press-work is good and so are most of the illustrations.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXI.

NEW YORK, SATURDAY, JULY 10, 1897.

No. 2.

ORIGINAL ARTICLES.

PRACTICAL DATA ON EUROPEAN HEALTH RESORTS AND SANITARIA.¹

By SIMON BARUCH, M.D.,
OF NEW YORK.

THE execution of a long-cherished plan to examine the practical workings of health resorts and sanitarium with which American physicians are more or less theoretically familiar, has enabled the writer to add to his knowledge on the subject much that is useful, and to remove much from his conception that is false and misleading. To transmit to his colleagues as briefly as possible the result of his investigations is the object of this communication, which will refer to representative resorts for the respective class of maladies in which they are prescribed.

THROAT AND LUNG AFFECTIONS.

Salzbrun.—Salzbrun is a town of about 3500 inhabitants, situated in Silesia about 1350 feet above the sea level. Being out of the usual line of travel pursued by Americans and Englishmen, it is not so well known as Ems and other resorts of like therapeutic qualities. The Kurhaus and its adjacent villas, hotels, and boarding-houses are situated in a sheltered valley of a branch of the Giant Mountains, embowered amid pine-covered hills which protect it against strong winds and lend to the air that balmy softness which allures sufferers from throat and pulmonary troubles. The soil is sandy, with a substratum of clay and rock, affording excellent drainage. In bright, sunny weather it is a cheery nook, but in rainy weather is somewhat dreary, owing to the somber hue of the green-clad hills and the exclusion of sunlight by the too assiduous cultivation of shade trees. The latter are indeed the glory of the place. The promenade of stately trees is occupied by a motley crew which, armed with cups, traverses it going to or returning from the spring. The terraced hills adjoining the Kurhaus are covered by a dense thicket of small firs, the aroma of which has long been famed for its soothing effect upon the throat, and adds immensely to the "suggestive element" of therapeutics, the influence of which is potent for good in most of these resorts.

The *real* advantages of Salzbrun are derived from its somewhat equable thermometric and barometric conditions. (Average temperature, 58.1° F.; barometer, 750 mm.) There is an average of about one rainy day out of every four, hence freedom from irritating dust is almost assured, an element which cannot be overestimated in the management of diseases of the respiratory organs. To this remarkable circumstance the chief advantage of Salzbrun over many other resorts for similar maladies may be attributed. The construction of promenades and walks affords evidence of skilful adaptation of the natural undulations and other scenic conditions to the use of invalids whose capacity for exercise is limited. Terraces are well graded and arranged in such manner that a large number of promenaders may utilize them without crowding. This is readily accomplished by reason of the thick forest of small pines which have been artificially cultivated wherever Nature proved deficient, thus screening each terrace from others quite adjacent. The ease with which feeble patients ascend these emerald-wooded hills strikes the observer on every side. Herein lies another advantage of Salzbrun. As a resort, the entire invalid population may and does live in the open air during the greater part of each day. When the Kapelle plays the morning choral at 6 A. M., the crowd begins its wanderings to the spring, moving gently along the promenade, engaged in conversation or observing the crowds. With the exception of meal times, which are frequent but brief interruptions, walking or sitting in the open air continues until 9 or 10 P. M. Milk and whey are used freely by the patients, always, however, in obedience to the physician's directions. The preparation and disposition of milk is an important industry here. The milk is obtained from cows, goats, asses, and sheep. Kefir, whey, plain or combined with iron, are furnished at the larger springs from clean cans, cold or warm, being dispensed by prettily attired dairy maids, who present a strong contrast to the male dispensers standing at the wells furnishing the mineral water.

It is worthy of mention that the entire dairy department, supplied with a centrifuge and sterilizers, is under the supervision of a chemist who applies all modern methods to its purification, while the health of the animals furnishing the milk is carefully guarded by a veterinary surgeon. About 30,000

¹ Read at a meeting of the Northwestern Medical and Surgical Society of New York, May 19th, 1897.

liters of cow's milk are consumed in a season; this does not include asses' milk (for which a similarity to human milk is still claimed here), or sheep's milk, which is said to be exceedingly rich in cream. The mixture of whey with the warm water of the Obersalzbrunnen is recommended by physicians here as an "expectorant" and laxative. Many patients may be seen sipping this combination at the spring. The hydrotherapeutic appliances of this kurort are primitive; a modern apparatus is promised by the management.

A novel department may be found on the hillside near the promenade. It is the "Gurgel pavilion," or gargling hall. This is built over the "Mühlbrunnen," which has the reputation for great efficacy as a local application in affections of the nose, throat, and larynx. There are separate halls for males and females, each being divided into compartments. The latter are about eight by four feet and contain a small gutter, above which is fastened a bar which is grasped by the patient's left hand, while the right holds the cup which supplies the mouth with the gargle. The head is thrown back, as usual in these guttural gymnastics, and each patient laves his throat to his heart's content, expelling the fluid into the gutter, which is kept cleansed by a flowing stream of water containing some disinfectant or steam. The gurgling chorus which reaches the ear as one approaches this pavilion is unique. That the patients derive any real benefit, besides the cleansing effect from these applications, seems doubtful at least. It certainly amuses them and serves to while away the tedium of an invalid existence; it is done with punctual regularity before breakfast precisely as prescribed by the physician, therefore must contribute a strong mental element to the "cure."

The chief disadvantage of Salzbrun lies in its popularity (in 1895 the number of patients aggregated 4300). Last summer it was so large that people were uncomfortably jostled during the morning hours when the spring is most frequented. It would be wise to limit the number of patients, for many will be driven away by the discomfort of too close contact with similar sufferers.

The writer's experience with the food and service in the dining-room of the Kurhaus does not warrant him in commending it; but the lodging is most comfortable. Upon the whole Salzbrun may be safely prescribed as a useful resort for the milder forms of affections of the upper respiratory tract and in some cases of chronic or subacute catarrhal disturbances of the bronchiæ. In regard to the water, it is claimed that its large proportion of the bicarbonate of soda combined with an appreciable percentage of bicarbonate of lithia, and a considerable quantity of free

carbonic acid enhances tissue change by increasing oxidation; that it dissolves mucus and diminishes its formation. Empirically, the Obersalzbrunnen has demonstrated its value not alone in the catarrhal affections referred to, but also in gout, lithiasis, diabetes, and other affections connected with defective or abnormal oxidation processes. It is palatable and does not deteriorate when kept in well-stoppered receptacles. Hence, it is shipped in large quantities (one million bottles in 1895). Conversation with the patients, one of whom was a case of aborted phthisis, diagnosticated and sent to Salzbrun fifteen years ago, satisfied the writer of the clinical value of the climate and water of Salzbrun in catarrhal affections of the respiratory tracts, and in cases of emphysema, when not too far advanced.

The congregation of cases of laryngeal phthisis in so small a resort renders it unfit for the treatment of diseases of the stomach and others referred to, because most of the latter being disposed to be hypochondriacal would surely be greatly depressed by the presence of the sad, pallid, and haggard specimens of coughing humanity seen here.

It may be mentioned that the cost of living is very reasonable in Silesia, the people are kind-hearted, the hotel proprietors being the very essence of urbanity, looking personally after the comfort of their guests. In the smaller hotels it seems to be the custom for the host to bid each and every guest at his table "Mahlzeit," which comprises all that may be required for the enjoyment of the meal.

In order to acquaint himself personally with a more noted resort the writer visited *Ems*. Unlike Salzbrun, Ems is somewhat contracted, lying in a narrow valley between spurs of the Rheingebirge, and being divided into two unequal parts by the river Lahn, which is bridged at two points. These hills rise to a height of from 500 to 1000 feet almost precipitously, presenting in some parts jutting rocks which seem to overhang the dwellings, but at most points these are covered with abundant foliage, varied by well-tilled fields and vineyards. Consequently there is no room for expansion in the direction of the hill sides, and patients are compelled to climb somewhat precipitous elevations in order to reach points outside of the village. Much has been done to overcome this difficulty, walks having been graded, and a cog railway having been constructed on the Mahlberg, upon whose summit pleasant well-shaded walks are abundant, affording the invalid the most enchanting views of the Rhine hills. Excursions up and down the Rhine, which is only twenty minutes distant, concerts, and the usual diversions of fashionable watering-places offer amusement and entertainment in a form which does not interfere

with the exacting demands of the "cure." Early hours for retiring being insisted upon by the physicians the concerts cease at 10 P. M., and begin at 7 A. M. The morning choral finds a motley assemblage, consisting of many nationalities, upon the stone pavements which separate the Kurgarten from the buildings containing the springs. This space is about the size of a small New York square, and is therefore very much overcrowded during the drinking hours. The springs are situated in a row of buildings which contain the shops usually found in these health resorts.

There are nine hot saline akalin springs, varying in temperature from 88° to 120° F., three of which are used for purposes of inhalation and six for drinking. The mineral constituents are feeble, the chief being 1 per 1000 of chlorid of sodium and 2 per 1000 of bicarbonate of soda, some containing as high as 500 volumes per 1000. The springs mostly patronized are the Kesselbrunnen and Kraehuchen, the former for inhalation and the latter for internal use. The Kaiserquelle appears to be the least used, judging from the number visiting it in the mornings when I observed them.

The most ingenious methods for inhalation have been devised and are in active operation here. The Schnitler apparatus delivers the Kesselbrunnen water into the patient's throat under pressure of half an atmosphere, the inhaling fluid consisting of some mild antiseptic balsamic agent, which is poured into the bottles. The Levin apparatus drives the inhaling fluid under a pressure of four atmospheres into the inhaling apparatuses; the latter are placed in rows upon a table, the patient sitting quietly in front of them inhaling. Other apparatuses for inhaling came under my notice in the splendidly arranged Quaehl Inhalatorium, which contains sixteen Jahr's apparatuses for inhalation of fluid medicines and saline or acid solutions, which are atomized into the finest spray; ten Dupont-Matthew machines for the inhalation of compressed air and expiration into rarefied air, with or without medicinal agents, all being prescribed by the medical attendant; two machines for inhaling oxygen, pure or mixed, according to prescription; three Waldenburg's apparatuses, and one Rossbach-Zobeibier respiration chair for lung gymnastics.

The most remarkable inhaling apparatus I observed is the Wassmuth inhalation, which offers facilities for inhalation of finely atomized fluids, chiefly Ems waters and balsams, to eighty persons, who may move around or sit down quietly and occupy themselves in a well-ventilated room.

A solution of chloro-borate of soda, devised by Professor Fresenius, is the favorite inhaling fluid. I found it agreeable, and, contrary to my preconceived

notions, distinctly felt the effect upon my bronchial tubes in promoting expectoration.

The Quaehl Inhalatorium is capable of affording 110 patients facilities for inhalation. The therapeutic indications are as follows:

1. Oxygen inhalations are used in dyspneic conditions and in catarrh, emphysema, and asthma; also, in chlorosis, leukemia, and gout.

2. Inhalations of compressed air are applied in bronchitis, asthma, pleuritic exudates, and in phthisis. Exhalation into rarefied air is applied in bronchitis, emphysema, and asthma. In most of these diseases a combined method is applied.

Another large institution is Goebel's Pneumatic Inhalatorium, in which hydraulic pressure is utilized and the air inhaled is not only warmed but cleansed by passing through a Wolff flask. The apparatus is automatic, and serves twenty-one persons; the water for inhalation is constantly renewed; the inspired air is not drawn from the room, but from the external air.

That there is a positive effect upon the air passages produced by these inhalations I am fully convinced by personal trial, but my observations upon their therapeutic effects are not sufficient to warrant any reliable deductions.

No treatment is administered in these principal inhalatoria without a physician's prescription. Dr. Geisse and his son, who are English physicians of long residence at Ems, offered me every facility by personal guidance to examine these institutions.

Ems is very hot in midsummer, but the air is pure and the nights are usually cool. There are many beautiful excursions, since it lies only half an hour's ride from the Rhine.

PHTHISIS.

Germany is the birthplace of the systematic treatment of phthisis by the hygienic, dietetic, and climatic method. Perhaps the most gratifying results observed in the treatment of chronic diseases are obtained in the famous institutions at Goerbersdorf, Falkenstein, Rupertshain, Rheiboldgrun, and others. A brief outline of these may interest you.

In Goerbersdorf, a small village lying in the mountains of Silesia, are situated the largest sanatoria for phthisis. Among these is the great institution built by Herrmann Brehmer. The enormous building is constructed of brick, and almost its entire façade is covered with glass-enclosed verandas. The grounds occupy 600 acres, and cost several million marks. Here the indefatigable pioneer of modern phthisis-therapy spent his whole life, and obtained the most favorable results. Unfortunately his heirs are unable or unwilling to leave the management of the institution in the hands of its capable medical director. I

was unable to obtain more than a very superficial idea of the institution. It contains facilities for treating every stage of phthisis, including a very crude apparatus for hydrotherapy, consisting of a shower-bath similar to that I saw later at Falkenstein. The physician stands in an adjoining room which is connected by a speaking tube, and directs the duration of the shower. But there is no thermometer to indicate the temperature of the water. Still they claim good results from hydrotherapy, and regard it as a powerful auxiliary. The method pursued here is somewhat indicated by an inscription upon one of the walls which reads, translated, "Patients do not come here to be amused, but to be cured." Brehmer always discouraged the association of phthisical people with the well, because the latter offer temptations to the former, which lead to transgression of his rules. Patients are encouraged to amuse themselves with innocent games, singing, dancing, etc., provided the physician's consent has been obtained.

Time will not permit a more extended description of this pioneer-institution for phthisis-therapy. The author of the method, Herrmann Brehmer, has passed to the great majority, but his teachings live and have most able exponents in Dettweiler, Roempler, and others.

The most modern sanitarium for phthisis, which I have visited, is also situated in Goerbersdorf. During the past twenty years it has been conducted by Dr. Theodor Roempler, a man of high attainments and the very essence of kindly courtesies. The institution being a model one is worthy of some descriptive details. It lies in a beautiful valley, embowered amid pine-covered mountain peaks. The grounds consist of 368 acres of land and 115 acres of forest. The former is tastefully laid out in walks and gardens, which may by an ingenious arrangement be sprinkled in a short time and thus become freed from dust. There are covered colonnades and a Wandelbahn for walking in inclement weather. The Liegehalle, a rest hall, being in a protected part of the building may be used in all kinds of weather for the air cure. The buildings are chiefly frame and contain 100 dwelling-rooms, which are heated by water, as is also the large winter or palm garden. The dining-room seats 200 persons and is attractive in all its appointments. Water is obtained from a stream issuing from the mountain peaks 300 feet above the valley. Laboratories for bacteriological work, a steam disinfecting apparatus, good diet, ventilation, and all the most approved methods combine to render this a perfect modern sanitarium for phthisis, which is capable of treating patients at all seasons. Roempler claims with justice as the result of his ob-

servations that the earliest possible removal of the consumptive from his unfavorable environment to the pure mountain air will most surely conduce to his recovery in a few weeks, while later action would defer it in proportion to the delay. Everything in the institution is under Dr. Roempler's control, he being the sole proprietor. He claims that tuberculosis depends not so much upon infection as upon the condition of the soil upon which it is implanted. He agrees with Hueppe that the cause of infectious diseases is always internal, as in the condition of the cells and tissues which the older writers called predisposition. He does not compare the Koch bacilli, as does Cornet, to bullets which may strike down any one, and from which many may and do escape, but rather to a spark whose devastation depends upon the quality of the material upon which it falls. If the seventh part of the human race dies of phthisis, and every fourth individual of tuberculosis, how difficult it must be for the other portion to escape, if it were not for the need of a good soil upon which infection may produce its sad fruit. These are trite observations now, but Roempler battled for them many years ago. He does not claim any special advantage for high altitude as do many others, but attributes success, as does his preceptor Brehmer, chiefly to proper hygienic, dietetic, and methodical treatment. That the latter not only cures but prevents phthisis Roempler has shown by the municipal statistics of Goerbersdorf.

During the century ending in 1889, seventy-two persons died of phthisis in Goerbersdorf; during ten years of the period fourteen persons died of the disease, while during the last ten years, despite a doubling of the population, the number of deaths was only five since 1875. Roempler, who knew and saw every consumptive among the inhabitants of the village since that year, states that of 207 deaths only 11 died from phthisis. During the same period 19 persons died of old age, *i.e.*, between the ages of 70 and 91. During that same period 933 patients died of phthisis in the Goerbersdorf institution. This demonstrates the fact that the inhabitants, though often in contact with phthisical patients, possess an immunity which, in his opinion, is due to their outdoor life, berry picking being a favorite occupation. Roempler insists that the fear of contagion is overdrawn, and that the intelligent public *would derive more benefit from instruction in a proper mode of life, proper respiration, nutrition, and care of the skin than from the latest discoveries in bacteriology.* My brief interview with this interesting gentleman brought many things to my practical appreciation which had hitherto been overlooked.

The chief aims of treatment are rest and exercise,

diet, open-air life and hydrotherapy. No patient having a temperature above 99.5° F. is allowed to exercise. Those who are permitted to leave the institution receive instruction to walk upon the carefully constructed roads which contain landmarks and sheltered seats, and which in winter are swept clear of snow. They are cautioned not to fatigue themselves. Rest in the open air appears to be the chief therapeutic agent. Lounging chairs are comfortably placed under the balconies, which have a southern exposure, and a portion of which is inclosed in glass for the worst cases. There is also a dressing-room adjoining the balconies, in which patients are enjoined to change their clothing when perspiring too freely after their walks before they occupy seats on lounges. Well protected by clothing and furs in winter, and appropriately clad in summer, the patients having temperature elevation recline upon lounging-chairs from the time they leave the breakfast table until the dinner hour, and again in the afternoon until supper. Patients presenting temperatures above 100° F. have their meals served while in the chairs. Nurses are in constant attendance. At stated intervals patients are made to rise and pass through a system of lung gymnastics, which is mild yet effective. After supper the patients rest awhile, and then retire to their chambers. The latter, being amply provided with windows, are ventilated during the entire day. An hour before the patients enter their rooms the latter are heated, the windows having been closed. The patients having temperature above 100° F. are now carefully undressed by the attendants, others undressing themselves. After being well tucked in, the windows are opened and are kept open during all seasons. Attendants watch the patients during the night and see that they are properly covered and that the face alone is exposed to the cold air. Before the patients rise the windows are again closed; the rooms are so heated (in winter) that there is no uncomfortable exposure. After the rooms are vacated, the windows are again opened and remain open all day. Bed clothing is aired and the rooms are carefully swept. Everything is scrupulously clean and sterilized. The beds, pillows and mattresses are often subjected to superheated steam, also the clothing of all patients leaving the institution.

Falkenstein is a small village lying about two hours by rail and wagon-road from Frankfort-on-the-Main. Its being the residence of the widowed Empress of Germany and of Baroness Rothschild would indicate that Nature has been lavish in her gifts to this mountain region. Dr. Dettweiler, who with Brehmer is a pioneer of dietetic and hygienic phthisis-therapy, has built here a private sanitarium,

capable of containing fifty patients which is resorted to by phthisical patients from all parts of the world.

Dettweiler does not favor large institutions, 100 patients is the largest number he would sanction. In this respect Schroetter of Vienna differs from him, being engaged in the construction of an institution for 300 patients, which is to be so arranged and governed that each patient shall have individual care. The principle of rest for cases having temperature elevation is rigidly enforced. The rules of conduct and treatment described as existing in Dr. Roempler's sanitarium are in force here. Dettweiler and Brehmer having been the original exponents of the rest treatment, the former carries the principle of rest to the utmost extreme. Whether the patients are stretched upon their lounging-chairs or at meals absolute silence is insisted upon. Even coughing is forbidden. When I remonstrated with Dr. Dettweiler against this seeming cruelty, he asked me if I would scratch my head in a room-full of people every time it itched. He teaches the patients to resist the desire to cough to the utmost. An embellished tablet hanging on the upper wall of the Liegehalle contains the following verse composed by a cured patient:

"In dem Tempel der Bacille
Herrsche musterlose Stille,
Walte Lust und Heiterkeit,
Dann ist die Heilung nicht mehr weit."

Each patient has a bottle for expectorations. The house is scrupulously neat and clean. Everything is sterilized. All the table utensils are carefully subjected to prolonged boiling (before each meal). The smallest details of the patient's life are controlled by the supervising physician, and nothing of any importance is left to his or her judgment. The daily exercise in the open air, the use of lung gymnastics, the administration of stimulants, even the changing of garments are all under the direction of the attending physician. Dettweiler says the physician who wants to manage successfully such an institution must himself be a good man, the possessor of a big heart and much patience, and he must be supplied with all the instincts of a "shepherd's dog." The relation of teacher and pupil, in the fullest and best sense of the word, must exist between the physician and his patients, and, without entering into the field of popular medical lectures, the patients should be taught to understand the physiologic and hygienic laws which it is so essential for them to follow if they desire to come out victorious in the battle with the bacillus of tuberculosis. The physician's office should be the patient's confessional chamber, and every possible effort should be made among the patients to foster implicit confidence in and strict obedience to the physician.

A few patients who can afford such a luxury live in neatly constructed huts, which revolve and thus easily remove the open portion from the wind or driving rain. A New York patient who occupied one of these huts informed me that he was improving in this cold climate, after being injured by the climate of Nice. Hydrotherapy is practised very crudely. A small room, with a cement floor shaped into a basin, receives the nude patient, who stands under a shower eighteen inches in diameter. The attendant draws the cord and the patient receives a fierce cold shower. This is repeated daily. The courteous attendant in reply to my anxious inquiry regarding the temperature and duration, replied that "the water is just as it comes from the mountain, and the time is left to the judgment of the physician." My inquiry regarding the exact temperature of this water was satisfied by a bath thermometer being brought from an adjoining room and placed under the flowing water. It registered 58° F., and this in midsummer. In winter it registers about 45° F. Dr. Blumenfeld, the courteous first-assistant of Dr. Dettweiler, assured me that patients bear the shower very well, after being somewhat improved by the hygienic and dietetic treatment pursued for a few weeks. I regretted to discover this crude hydrotherapy, because a most valuable element of treatment is lost to feeble patients and applied very late in those who may bear it better. The method I have introduced in the Montefiore Home, in this city, where it is practised with much success, is far more rational. Here every patient is at once subjected to mild ablutions or rain baths, after carefully widening the cutaneous vessels by hot-air baths short of perspiration. Day by day the reactive capacity is enhanced, the heart invigorated, the respiration deepened, and the nutrition improved. Gain of weight and the patient's appearance testify clearly to these results. Some patients refuse to take these baths unless they are allowed to receive low temperatures. Sixty-five degrees F. is the lowest I prescribe, but some of the Montefiore patients have become so inured to them that they bear 45° F. with impunity, as I am informed by Dr. Fraenkel, and have observed myself in one case. This adaptation of temperature to the varying conditions of the patient and the gradual accustoming of patients to the shock and reaction, which I regard as imperative whenever the agent is applied, would seem more rational in phthisis than the application of a fixed and very low temperature which must exclude many otherwise favorable cases from the treatment.

An excellent luncheon at Dettweiler's sanitarium convinced me that the cuisine and attendance are unexcelled. Dr. Blumenfeld stated that the tone of

the institution is one of hopefulness and good cheer. Good food, pure air and water, and ventilation of bed-rooms combine to produce the excellent results obtained.

Institutions for the Middle Classes.—While investigating the subject of phthisotherapy my attention was drawn to the great movement for Volkheilstätte or people's sanatoria, now in full operation in Germany. With a view to observe their workings, I visited two of these institutions.

Ruppertshain.—This is a small institution established under Dettweiler's auspices for the purpose of affording working people the means of obtaining the same treatment which at the Falkenstein Sanitarium can be obtained only by well-to-do people. The cost at Falkenstein ranges from \$3. to \$5. per *per diem*, while at Ruppertshain the expense ranges from 62 cents to \$1.50 per day, which is not sufficient to pay expenses. This noble institution, which is still in its infancy, being prepared for only sixty patients, and harboring at the time of my visit only thirty patients, received its chief impetus from the bacteriophobia of a rich but generous woman. Dr. Hirsch, a philanthropic physician of Frankfort, had founded a small sanitarium with twenty beds at Falkenstein. This was bought for \$15,000 by the Frankfort Association for Convalescents. It was situated opposite the villa of the Baroness Rothschild, who, fearing the near proximity of an army of bacilli, offered \$50,000 for the property, razed it to the ground, and disinfected the latter. Upon this capital the association was formed which now controls this beneficent institution, its members being chiefly among the best citizens of Frankfort and the neighboring towns. The Empress Frederick and the Baroness Rothschild are active contributing members who often visit the institution. (The latter established a separate kitchen in which the Jewish dietary and cooking laws could be strictly observed for the benefit of any Jewish patients desiring it.) Patients are sent by mutual benefit societies in Frankfort, Hesse, and other cities, which pay for each member. They are usually taken on eight-days' trial to ascertain the fitness of the case, which also is certified to by the previous medical attendant.

Dr. Nahin, a former assistant of Dettweiler, being medical director, all the regulations of the Falkenstein Institution are strictly followed, the discipline being more strict. The water treatment is rational here. Patients are first subjected to daily dry friction, then cool, wet friction, and douches follow after their reactive capacity is established.

Many such institutions, called Volksheilstätte, have been established in Germany by sick insurance

companies. I was informed that Koch was expected to assume charge of a large one at Hoechst in the Odenwald.

A similar institution is located in Goerbersdorf, called "Krankenheim." This originated with and is in charge of Dr. H. Weicker, whom I had the pleasure of visiting. This is a modest institution; beginning with nine patients the number increased in 1896 to 185. One-half of the patients are sent by various sick benefit, and other associations, the other half are people of moderate means who defray their own expenses. The building was intended for a villa and is surrounded by fine old trees. Each room is occupied by two or three patients; the walls are painted in oil, and the rooms heated by porcelain stoves. The beds are of iron with wire mattresses. Woolen blankets used on the beds are enveloped by covers of washable material. Spittoons, in the shape of sand-glasses, are secured to the walls about the height of a man's chest. These are disinfected by lysol solution. Accidental expectorations on the floor are not allowed to be touched by the patients, who are enjoined to call an attendant with lysol solution. There are no spittoons in the bed-rooms, because patients were in the habit of indulging in shooting matches which soiled the floor. Cups, which must be held before the mouth, were therefore substituted. Each patient must clean his hands with a nailbrush before, and rinse his mouth with salt water before and after meals. In short, the strict discipline regarding the patient's conduct, his treatment, his occupation, diet, rising, and retiring, are given in writing. Separate groups elect their presiding officers, who are responsible for reports. Dr. Weicker endeavors to keep the patients busy all day with the "Kur," the principal part of which consists of lying in the open air. With regard to occupation Weicker gave me good reasons for differing from Wolff, and others, who favor some light work. How can tuberculous patients be expected to protect a crop against an approaching rain storm, for instance? At most he favors retaining some of the actually convalescent patients for farm labor in order to render their recovery more permanent than it would be if they returned to other unfavorable home environment. The hygienic education of the patient is made permanent; it not only furthers his restoration to health but maintains the latter, and converts him into a missionary of hygiene. The German legislature passed laws in 1889 for the furtherance of sick benefit and insurance companies, and for the authorization of the construction of sanatoria for consumptives. It has been demonstrated that among 1000 deaths at the ages from fifteen to sixty years, 322 are from consumption. If the ability to labor of each of these

sick people could be increased three years, many millions would be saved, inasmuch as one-third of the entire population is involved.

In our own country similar conditions prevail, with the sad additional fact that mutual benefit societies are not so numerous as in older countries. No greater beneficence can be bestowed upon suffering humanity than the erection of sanatoria for phthisis by private and public aid to which people of moderate means could be sent in the *initial* stages of the disease.

The municipal authorities should erect a hospital for phthisical patients, in which all modern therapeutic methods may be utilized. To this all initial cases of phthisis reported to the Board of Health should be sent. This would *seem* a great hardship. But careful consideration would show that a focus of infection would then be removed from the "laboring-man's" home to which he may be returned in an improved condition, and imbued with the importance of observing strictly hygienic rules which would prevent the lighting up of any smouldering ember of his disease in himself or family. Tempting as is this subject time does not permit of my dilating upon it.

The late Dr. Paul Kretzschmar of Brooklyn published an appeal for the construction of such sanatoria in 1888, which presents the subject in the clearest manner. The efforts of this enthusiastic philanthropist should be borne in mind whenever the subject of institutions for phthisis is discussed. They have indirectly borne some fruit in the building of the Seton Hospital, which was organized under the lamented West Roosevelt, and is now under the care of that able clinical teacher. Dr. Frank W. Jackson, chief of the Vanderbilt Clinic.

HEART DISEASES.

The treatment of cardiac diseases has found a large field at Nauheim, which I visited for the purpose of studying the carbonated saline baths utilized there.

Nauheim is a small town lying at the foot of the Taunus Mountain, and supplied by strong saline springs from which salt is made by evaporation. Having fine parks, excellent hotels, and good physicians, it is an ideal resort for cases requiring rest and treatment. The brothers Schott, following the initiative of Professor Beneke, discovered that many neurotics who used the baths improved not alone in their depreciated nerve-tone, but gained in cardiac vigor. By careful study the late Dr. Theodore Schott evolved a treatment of saline baths and Swedish (resisting) movements, the effects of which upon certain cardiac diseases are indisputable. Some of these baths are quite efficient in functional neurosis, and chronic rheumatism.

Briefly stated, the principal springs are the Karlsbrunnen for drinking, containing $16\frac{1}{2}$ per cent. chlorid of sodium, 1 per 1000 of chlorid of calcium, and considerable free CO_2 ; and the Ludwigsbrunnen, which is a gaseous muriated water. The *sprudel* issues from the earth in a strong stream; it contains $2\frac{1}{2}$ to 3 per cent. of chlorid of sodium, 2 to 3 per 1000 chlorid of calcium, and a considerable quantity of free CO_2 , and its temperature ranges from 83° to 96° F. I visited the sprudel baths under the guidance of Dr. Goehler, the first assistant of Dr. Groedel. They are strong saline, effervescent, carbonated baths, which rush with great force into tubs sunk in the floor. These strong gaseous baths have the effect of greatly stimulating the cutaneous vessels, thus counteracting the chilling effect of low temperature. I saw a full bath of 82° F. borne for eight minutes with comfort, the patient emerging from it with a ruddy hue. The *rationale* of these baths has been somewhat obscurely stated by Schott to be a reflex stimulating influence upon the cardio-inhibitory or regulator nerves, improving the quality of the pulse.

Dr. Bezley Thorne and Sir William Broadbent claim that the favorable effect upon the heart and circulation is due to a dilation of the muscular arteries, and subsequently those of the skin by which the heart is relieved from backward pressure. But this would not increase the arterial tension, which is always observed. The experienced hydrotherapist finds a more simple explanation in the fact so often demonstrated that the first impression of cold upon the cutaneous vessels is their contraction. This increases arterial tension by driving the blood to the interior. But it is soon followed if not prolonged, or if neutralized by friction or other stimulus by a dilation which is not due to a paralysis of the vasoconstrictors, as in the case after warm baths, but to the stimulation of the vasodilators and consequent tonic dilation. Dr. Woods Hutchinson, Professor of Comparative Anatomy in University of Buffalo, has recently pointed out that it is probable that the cutaneous vessels possess inherent contractile power, which he denominates the skin heart. This is in accordance with my own clinical observations repeatedly presented before you and elsewhere. In my paper on "The Management of Pneumonia," read before you, I held that the result of local applications of cold to the skin in fever gives rise to an active dilation with maintenance of the tone of the vessels, an active hyperemia, by reason of which the blood is propelled more vigorously through them. The heart is thus relieved, I said on that occasion, not by a *vis a tergo*, as is the case after digitalis, but by a *vis a fronte* formed by broadening

the blood stream in the cutaneous capillaries whose enhanced tonicity aids at the same time in propelling the blood onward; arterial tension is increased, as is evidenced by the better feeling of the radial arteries. This I regard as the *rationale* of the cold compress in pneumonia and of cold baths in infectious fevers, and is the *rationale* of the Nauheim saline baths. The effect is enhanced in the latter by its saline and gaseous constituents, which stimulate the vasodilators just as friction stimulates them in the Brand bath. This is the simple and, I believe, correct explanation of the effect of the Nauheim baths, which afford the heart so much rest, steady its contraction and improve its nutrition by the general tonic effect. These are greatly enhanced by the Swedish movements, the quiet life, careful attention to diet and general hygienic surroundings.

Hot Saline Springs.—This class of springs, which is favored by patients suffering from rheumatic troubles, abounds in Germany. As a good example, I may cite Aix-la-Chapelle, which I visited. This town lies on the main line between Cologne and Paris. The great advantage of Aix-la-Chapelle lies in the fact that nearly all the baths are situated in fine hotels. There is no necessity, as at Aix-les-Bains, for patients to be carried in sedan chairs from the spring to the hotel, as most of the hotels are provided with elevators and invalid chairs. Dr. Beissel claimed other advantages over Aix-les-Bains. The latter, being too gay, offers temptations to invalids for deviating from strict discipline, and that its waters, containing alum and lime in combination with the sulphur, are unfitted for drinking.

Dr. Beissel courteously accompanied me to all the old and new baths. The latter were being constructed in the most approved manner, heated by the water from the springs, which furnish an inexhaustible supply. I took a hot douche-bath, which resembled those for which Aix-les-Bains is so famous. The doucheur holds the hose with his left hand, with the right he envelopes the steam issuing from it and directs it to various parts of the body, grading its force by scattering. A fan is held by the patient to protect the face against scattering hot water.

The entire city is underlaid by the hot springs; in a distance of 1316 meters, the water issues from ten springs, while in the neighboring village of Burtscheid, a line of 1680 meters furnishes twenty-eight springs. Dr. Beissel pointed out to me the Kaiserquelle which has a temperature of 131° F. The coldest spring in Aachen is the Cornelius spring, the temperature of which is 110° F. Chemically these waters are alkaline, sulphurous, chlorid of sodium waters containing little gas, a small quantity of iodine

and bromin. In Burtscheid, a village lying about one mile from Aachen, the springs are of the same chemical composition, but hotter, the hottest being the Muhlbad, the temperature of which is 163° F. I saw children and women take this water to their kitchens in order to save fuel in cooking.

The affections chiefly treated here are chronic skin diseases, chronic metallic poisoning, gout, rheumatism, and syphilis. Indeed the value of these baths in the latter disease have produced such an afflux of syphilitics that the town has obtained quite an unenviable reputation, which prevents purely gouty, rheumatic, and other patients, from frequenting it. At least so I was informed.

My time being nearly exhausted I shall refer briefly to that portion of my subject, in which I am most deeply interested, *viz.*: hydrotherapeutic establishments and resorts. Of these I visited a large number in Germany, Austria, and France. Most of these institutions are situated in beautiful mountain nooks. There the patients may enjoy the purest air and feast their eyes on the most lovely scenery. Some are constructed on a very large scale. The great Augusta Victoria Baths at Wiesbaden is probably the largest institution. Among these may be mentioned Kaltenleutgeber, near Vienna, where the famous Winternitz presides, and Dr. Koehler's institute at Eisenach. The latter is a magnificently appointed building occupying a promontory from which the eye may roam over the loveliest scenery in all Germany, verdure of the deepest hue, well-tilled fields, romantic gorges, nature and art commingling, while just above upon a still loftier eminence lies that historic castle, the Wartburg, the home and refuge of Luther in the days of papal persecution.

Elgersburg, in the Thüringen forest, where the genial Barwinski has long comforted and brought back to health invalids sent by the most famous physicians in Germany, is one of the enormous "wasserkur" establishments, dating back half a century.

At or near each of these three towns mentioned, there are from three to ten smaller water-cure establishments. Allow me to state what is probably familiar to many of you—that the word water-cure means simply water-treatment, the last word being derived from cura—to care for. Its meaning differs, therefore, materially from the English word, cure. I was not favorably impressed with the methods pursued in most of these institutions. A lack of precision, already referred to in the treatment of phthisis, is evident. Water is still administered here in a somewhat inexact manner, little regard being given to pressure, somewhat more, but not enough to temperature and duration. Among

twenty-eight institutions visited by myself, only three had pressure-gauges, none had any arrangement for ascertainably increasing with precision the pressure used, as may be done in the Hydriatric Institute of this city, in the German Hospital of Philadelphia, and other institutions in this country. Only four had fixed thermometers for ascertaining and regulating the temperature of the douches. Despite these apparent defects, the results obtained are marvelous, especially in gastric and nervous diseases. The reason for this success may be found in the fact that educated physicians preside over these institutions and do not entrust the treatment of patients to nurses, but either administer it themselves or supervise the water treatment. Of late years a more exact technic is observed, from which, doubtless, much better results will follow.

In connection with this subject it may be of interest to refer to the *Naturaerzte* with which Germany is now overrun. These are water-cure establishments conducted by all sorts of lay people, who have failed in other vocations. The largest institutions of this kind are in Chemnitz, and near Dresden, Saxony. These are presided over by physicians, and from them emanate most of the laymen who erect institutions. The great institution bequeathed by Zimmerman, a merchant, who claimed to have been cured by water, air, and diet after failure of the best physicians, was described in the *Medical Record*, in a letter contributed by myself, in the fall of 1890.

The sanitarium called Weisser Hirsch, near Dresden, is world-renowned. It lies about an hour from the city, on a wooded eminence occupying many acres of ground, owned and presided over by Lahmann, who is the high-priest of "natural treatment." It is unique in some respects. First, it has the poorest facilities for hydrotherapy which I saw in Germany. Second, it has an open-air cure, consisting of a fenced-in piece of woods, the soil of which is thickly covered with sand. Here men, completely nude, with the exception of light trunks, spend the entire day, playing ball or in other amusements, or lying on boards or cots. These people look bronzed and hearty.

Lahmann himself lives in a hut, the entire southern face of which is open; except in very inclement weather he wears no underclothing or socks, his feet being partly covered with the Kneipp sandals. This mode of dress is followed by most of the patients. Time will not permit further details. Thousands of people resort to Lahmann's institution with more or less success.

I visited some dozen institutions for "nature cure" in various parts of Germany; most of these are beautifully located, but being managed

entirely by laymen the treatment is very crude. It seems incomprehensible, as in Bettelsdorf, in Silesia, for instance, that a merchant is allowed to care for one hundred sick people without a physician. The director told me that his father was cured of rheumatism by water and diet after all the doctors had failed, hence his present vocation. While in Prussia these *Naturaerzte* are permitted to have institutions, in Saxony they are compelled to have a resident medical man.

The extent of my subject has admitted of but brief reference to each portion. It has been my aim to present to you a sketch of my observations in these health resorts which may give you a glimpse of their condition and methods, rather than enter into any theoretical discussion of the latter. In conclusion I may reiterate, as the result of study and observation of the subject, the statement made in my article on mineral springs in Hare's "American System of Therapeutics," Vol. I:

1. The accuracy of the results of balneotherapy is woefully marred by the bias due to one-sided study and observations of men, who, be they ever so honest, are more or less misled by their environment and by their advocacy of waters with which their interests are intimately interwoven.

2. The multiplicity of elements in the therapeutic problem, as bathing, drinking, and the various ingredients in the waters, climate, surroundings, diet and changed mode of life, render safe deductions difficult.

3. The results from drinking mineral waters containing, with the few exceptions of purgative and the strongest saline waters, a minimum of chemical elements, are to be ascribed chiefly, if not entirely, to their hydrotherapeutic effect—being practically the same as drinking pure water in the same large quantities.

4. The result from bathing in mineral waters is chiefly due to the temperature of the water and duration of the immersion. The experiments of Lehman, and others, with baths of ferrocyanid of potassium showed that not a trace was found in the urine, and after lithia baths not even the spectroscope could discover the faintest evidence in the urine.

5. Nevertheless, I believe that visits to mineral springs are of great value, because of the improved hygienic, atmospheric, and scenic conditions, the freedom from care and absence of business pressure, together with the stimulus of amusement and diversion, regular habits, strict diet and hygiene, drinking of large quantities of water which sweeps out effete material, and the valuable effect of baths which is enhanced by the saline, gaseous elements of the water.

A careful study of American springs (Hare's "System of Therapeutics," pp. 515-533) convinces me that we have in this country some of the highest types of mineral springs, and that if the physicians at these resorts would insist upon precision in drinking, diet, exercise, rest, sleep, and the proper adaptation of hydrotherapeutic effects, with the same emphasis as do the physicians at the European resorts, the annual exodus from the country would be greatly diminished.

A fertile field is open to the medical profession of this country, a field which if properly tilled not only would bear good fruit to numberless invalids, real or imaginary, but which would give recreation, change of scene, and work, and satisfactory financial results to many colleagues who now labor in crowded towns and cities during the hot summer months.

HEADACHES FROM NASAL CAUSES.¹

BY SARGENT F. SNOW, M.D.,
OF SYRACUSE, N. Y.;

AURIST AND LARYNGOLOGIST TO THE HOUSE OF THE GOOD
SHEPHERD, SHELTER FOR HOMELESS WOMEN, AND TO
THE SYRACUSE FREE DISPENSARY.

IN this paper I do not intend to dwell to any extent on the history of individual cases but to give a sort of abstract of experience, selecting as a basis for conclusions only representative cases which have been followed up carefully, a table of which is appended. Neither will I include those headaches associated with inflammatory disease of the accessory cavities, this latter affection having been so comprehensively written up during the past three years.

In a paper on "Hemicrania"² I have called attention to pressures within the nose as a cause of sick headaches and neuralgic affections. At that time it was felt that perhaps an apology was due for venturing on a subject so nearly barren of literature. Now I am pleased to find that others both here and abroad are giving the nasal passages due credit. As early as 1886 Dr. Harrison Allen of Philadelphia published a paper on "Headaches Associated Clinically with Chronic Nasal Catarrh."³ The essay was comprehensive, replete with valuable deductions, and without doubt was the first published on the relation of headaches to intranasal conditions. In a foot-note he mentions a discussion touching on this subject which took place at the New York Academy of Medicine, January 21, 1886, but after his paper was written. In 1888 Dr. John O. Roe contributed a paper, entitled "The Frequent Dependence of Persistent and So-called Congestive Headaches upon Abnormal

¹ Read before the American Laryngological, Rhinological, and Otological Society, Washington, D.C., May 1, 1897.

² *New York Medical Journal*, March 31, 1894.

³ *THE MEDICAL NEWS*, March 13, 1886.

Conditions of the Nasal Passages." ¹ Aside from these, and the mention made of the nose as a factor by Dr. Wharton Sinkler in an excellent article on the "Etiology and Treatment of Migrain" ² I have been unable to find record of any paper relating to this subject by American writers until that produced by myself in 1893.

From all data at command, I think Dr. Hack of Freiburg (quoted by Sinkler) was the pioneer in Europe in recognizing the fact that headaches sometimes come from nasal causes. Maximilian Bresgen of Frankfurt wrote a paper on "The Headaches in Nose and Throat Diseases," ³ a copy of which he has courteously sent me. This article is very clear and concise, pointing out with detail the regions which most commonly produce headaches, and their great frequency as a symptom in nose and throat diseases. At a meeting of the British Laryngological Association, held in London, October 12, 1894, Mayo Collier reported a case of "Headache from a Diseased Middle Turbinal." Dr. J. H. McCassy of Dayton, Ohio, ⁴ in connection with his experience as superintendent of the Kansas State Insane Asylum, says: "As might be expected, headache is alarmingly common among the insane. I am convinced that hypertrophies, vasomotor rhinitis, polypoids, deflections of the septum, catarrh of the ethmoidal, frontal, and maxillary sinuses, etc., are frequently causes of headaches, and in not a few cases of insanity."

For a number of years past the neurologist and the ophthalmologist have had full sway in the treatment of these cases. They have published many valuable books and papers and should receive due credit. One of the recent productions is Corning's on "Headaches and Neuralgia." The author does not even speak of a possible nasal cause in his classifications, though he mentions at considerable length those termed nervous, toxic, bilious, etc. Errors of refraction must, of course, be corrected, but the rhinologist should have a place in this line of work. I have selected from my records thirty cases of cephalalgia that have been referred to me as a last resort by different physicians. These patients on examination appeared to be fit subjects to work upon and treatment was instituted. They do not include those met with in any hospital or dispensary practice, or those who have been mentioned incidentally during the course of ear or throat treatment, where nasal surgery has been a prominent feature, and by means of which their headaches had been cured. In this group of thirty patients I find

that seven claim to have received relief to the extent of about 40 per cent., five 75 per cent., ten 90 per cent., and eight 100 per cent. A careful review and study of their records bring out some interesting points. Sixteen were treated between 1891 and 1894, giving from three to five years in which to judge of results. Ten of these show from 90 to 100 per cent. relief of their headaches. Twenty of the thirty cases were females. The youngest was seventeen and the oldest sixty-five years of age. Sixty per cent. of the whole number were from thirty to forty years of age. Seventy per cent. of these patients appeared to have hemicrania as a result of middle turbinate pressure. Of those reported as showing 100 per cent. relief, the whole number, eight, received a full and thorough operative course. Fourteen, because of their improved condition, stopped treatment before all the visible intranasal contacts and pressures were removed. The remaining eight had a complete operative course, but owing to the sensitive condition of their membranes they are yet having some headaches, though four are found in the 90-per-cent. class. Another notable fact deduced from these thirty cases is that of the sixteen who received a full operative course, twelve report from 90 to 100 per cent. improvement. Experience with other cases not mentioned in this list teaches me that about the same ratio of improvement (75 per cent.) will hold good in all headaches from nasal causes, if each and every point of pressure or contact is thoroughly removed. Operative work on these patients is what gives quickest and most brilliant results. It should be carried out with the fact in mind that the nasal membranes are very sensitive and prone to swell, and a little more of the offending overgrowth than is necessary to absolutely relieve the pressure should be removed, though not enough to impair the natural function of the nose.

Hajek of Vienna attributes the headaches so commonly met with after tamponing the nose and in acute coryza to a stasis. His opinion is that the veins passing through the lamina cribrosa give off one large branch to the dura mater, turn, and again enter the nasal cavities; these become engorged, press against the brain substance, and occasion severe pain. Schreck of Munich looks upon hemicrania, due to nasal and postnasal causes, as partly attributable to the hindered flow of lymph and venous blood from the brain. Dr. Robert C. Myles of New York writes me that in his opinion "vasomotor disturbances of this region or compression of the small nerves in the bony canals of the cribriform plate by the artery or vein will cause headaches under certain conditions." This theory of stasis produced by a

¹ *Medical Record*, August 25, 1888.

² *THE MEDICAL NEWS*, July 19, 1890.

³ *Munch. Med. Woch.*, January 5, 1893.

⁴ *Cincinnati Lancet-Clinic*, September 5, 1896.

retarded circulation, coming as it does from three eminent and independent sources, should receive consideration. Perhaps it will explain why some twenty-five per cent. of our patients have an occasional return of their trouble after all visible pressures and contacts have been removed. According to some neurologists, it may be due to the fact that "all influences exerted upon the human body are to a greater or lesser degree cumulative, and the phenomena following these are proportionate to the response yielded by the receiving nerve-centers." Personally, I think that most of these recurring attacks are produced by the irritable and sensitive condition of the membranes, which favor congestion, with resulting pressure on sensitive areas.

In those cases of headaches from nasal causes which have come under my observation, but two can be recalled in which the patients at the time of their seizures did not show some point or points of contact within the nasal fossæ. Their relapses may be due to stasis as mentioned above. It has been noticed that they as well as others are kept very comfortable if weekly or biweekly stimulating applications be made in order to keep the relaxed and sensitive membranes in proper tone. The treatment that appears to act best in producing this result is a gentle spraying of the parts with iodole and ether, the patient being instructed to breathe through the nostrils quickly if the application produces too much smarting pain. Three grains to the ounce of this mixture is a good strength for these tonic treatments, and the same combination, preceded if necessary by a two-per-cent. cocain spray to allay smarting, is very efficacious in reducing acute or subacute nasal and postnasal inflammation. In fact, it is good in temporary turgescence from any and all causes.

Without doubt some cases of migraine are of the nature of "nerve storms" and are closely allied to epilepsy, but it appears very probable that these nerve storms are primarily brought about by some irritation of a nerve filament, such as is produced by contact of the inner surface of the middle turbinate body with the septum.

My paper on "Hemicrania," written in 1893, contained the proposition that there are a certain number of headaches which can be cured, or at least relieved, by the proper treatment of pressures or contacts within the nose. Added experience during the past four years, together with the observations of other workers, has amplified this idea until it surely appears that we are safe in advising those who come to us with a history of persistent or recurring neuralgia, clavus, sick headache, pressure on top of the head, or the deep frontal pain commonly termed

catarrhal headache, to have their nasal and post-nasal passages put in the best possible condition. I am about ready to believe that from 70 to 80 per cent. of all cases of headaches of hemicranial order are due to removable causes located within the nasal passages or adjacent air spaces.

As intimated above, the treatment *par excellence* for these obstinate cases in which we find evidence of nasal disease of whatever nature is the correction of that disease by the means indicated. If we have reason to think that the trouble comes from the accessory sinuses these must be drained. If the space between the septum and a middle turbinated body is too narrow, or if this same body is overgrown anteriorly or presses against the outer wall of the nose, preventing free access of air into or drainage of the sinuses, it must be reduced in some manner. If bony shelves, membranous or cartilaginous thickenings causing pressure are found, these should be taken care of. In some cases one fails to find any of these deformities, and perhaps at the time of examination there are no points of contact, but it will be noticed that the membranes are of a peculiar bluish-red color, and have a sensitive or relaxed appearance which is an indication that within the next half hour there may be some localized spot of pressure. This condition does not require operative interference, but will usually respond to persistent and stimulating treatment, together with proper regulation of the habits, manner of living, exercise, etc., and, according to Roe, if the patient resides in the Lake region, avoiding too great a quantity of night air in the sleeping apartment.

One word further, regarding those patients suffering from an attack of headache, who ask for temporary relief. Inspection of their nasal passages will perhaps show marked pressures in the olfactory region, which may be due to an acute or subacute inflammation without much chronic disease, and without osseous deformity or overgrowth. About ninety per cent. of these patients can be relieved in one or a few treatments by cleansing the nostrils, and using the iodole and ether mixture, preceded by a light two per cent. cocain spray, as described above. Sometimes this will have to be repeated in four or five hours, but one treatment usually breaks up an attack. Cases number 22 and 27 in the appended table well represent this class.

The desire to be brief has hindered me from quoting other authors, who have written on headaches, and forced me to leave out many things that I would have liked to mention; still I hope that proof enough has been brought forward to cause the rhinologist to take a more active interest in reflex headaches.

THE MICROSCOPIC EXAMINATION OF MILK.¹

By WILLIAM ROYAL STOKES, M.D.,
BACTERIOLOGIST TO THE HEALTH DEPARTMENT OF BALTIMORE;
LECTURER ON BACTERIOLOGY, BALTIMORE
MEDICAL COLLEGE;

AND
ARTHUR WEGEFARTH, M.D.,
PHYSICIAN TO THE NORTHEASTERN DISPENSARY,
BALTIMORE, MD.

BEFORE considering the benefits to be derived from the microscopic examination of milk, it may be well to consider briefly the subject of milk as an infectious agent. It is well known that the presence of the bacillus of tuberculosis has often been demonstrated in the milk obtained from tuberculous cows. Clinical experience, especially with babies and young children who derive their entire sustenance from this fluid, would also go to show that many cases of intestinal tuberculosis are due to drinking milk from tuberculous animals.

Milk also is a very favorable medium for the development of many other pathogenic bacteria, and the accidental introduction of such bacteria as the typhoid bacillus, the anthrax bacillus, or any other of the pathogenic organisms may give rise to the specific diseases caused by these germs in those who drink such a contaminated material. It is not the purpose of this paper to deal further with this subject, since the microscope could hardly be used as a routine method of deciding such conditions, even when present. The microscope is often of great

¹ From the laboratory of the Health Department, Baltimore, Md.

use, however, in detecting a serious contamination in milk, namely, pus; and the presence of this product of inflammation in any considerable quantity generally points to the existence of some inflammatory condition of the teats or udder of the cow supplying this fluid. Such a condition in cattle is known as "garget," and this disease has been studied by numerous observers, and the causes which bring about this trouble have been duly noted. This work was mentioned in a paper, entitled "An Epidemic of Purulent Inflammation of the Milk-ducts Affecting Seventy Cows," by W. R. Stokes and A. W. Clement, State Veterinarian, in which it was stated that most investigators consider garget as caused by some local injury to the teat or udder, followed by a secondary invasion of the injured area by the pyogenic bacteria. The organisms may cause an extensive inflammation, and the milk will then not only contain many pus cells, but what is more injurious, the various bacteria, which have produced the pus in the udder.

The above article also described an epidemic of purulent inflammation of the milk-ducts affecting seventy cows. This condition did not arise from any local injury to the udder, but seemed to be due to the infection of a few of the herd by means of a sore finger of a milker, and the gradual transference of the disease from animal to animal, through the hands of the other milkers. Garget is a far more frequent condition than many people suppose. The writers have been struck with the number of instances in which it has been detected in large or small herds supplying various individuals or communities.

One should not be too hasty in condemning a sample of milk merely because it contains a few pus cells. It has been the custom at the laboratories of the city Health Department of Baltimore to make a microscopic examination of the samples of milk as they reach the city consumer. The milk is first centrifugalized two and one-half minutes by means of the Lentz centrifuge. Ten cubic centimeters of milk is used in each tube. The supernatant fluid is then poured off and the sediment is spread evenly over the surface of an ordinary glass slide. The specimen is then dried over the flame of a Bunsen burner, or in a water evaporating oven. Ether is then applied until all superfluous fat is removed, and the slide is stained with Löffler's methylene blue. This method not only forms a ready means of detecting the presence of pus, but if the specimen be taken from any one cow, an excessive amount of pus cells can also be noted. The examinations are made with a one-twelfth-inch oil immersion lens. It has been found from a number of examinations that most

samples of milk mixed from a large herd will contain a few pus cells. On the other hand, when the samples have been taken from individual cows, many more pus cells have been found. Inspection of such animals later showed that such a condition was due to suckling calves, local abscesses, or purulent suppuration of the milk-ducts—processes which at times might have escaped even the notice of a skilled observer. From what has been said, it will be seen that milk as a general food product must certainly at times contain bacteria capable of producing disease.

Let us next consider the evidence in favor of the view that such bacteria when introduced into the intestinal canal may give rise to such conditions as acute or chronic gastro-enteritis. The writers are not aware of any experimental work upon animals which proves that the introduction of the ordinary pus organisms into the intestine will give rise to conditions resembling these just mentioned. We are in possession of some facts, however, which are perhaps quite as convincing.

Dr. Booker of Johns Hopkins University, in his most elaborate and complete researches on "Summer Diarrheas of Infants," brings out very clearly the relationship existing between certain forms of gastro-enteritis and the streptococcus. In a certain number of these cases which were marked by symptoms of general infection, the streptococcus was found in cultures from the intestines, and the presence of these bacteria could also be demonstrated in the various inflammatory intestinal lesions by means of special bacterial stains. Eleven cases of streptococcus enteritis were also mentioned as reported by other authors. There can be but little doubt, therefore, that the streptococcus is largely concerned in producing certain forms of intestinal inflammation, while the researches of Escherich and others show that this organism is only an occasional inhabitant of the intestinal canal, and when present that it is only to be found in small numbers.

In view of what has been stated a detailed account is offered of an epidemic of mild gastro-intestinal irritation in which the most reasonable explanation of the cause seems to be the drinking of milk containing the products of acute inflammation from a diseased cow. The following notes were kindly made by Dr. Henry Lee Smith of Baltimore during the absence of the writers from the city:

In one of the educational institutions of this city, some of the inmates were suddenly seized with marked nausea, vomiting, and purging. Dr. T. J. King was called upon professionally, and states that during the next few days a number of other children were similarly attacked, making twenty in all. The ages of the young girls were from eight to four-

¹ *Maryland Medical Journal*, January 9, 1897.

teen years, and the symptoms were not of sufficient gravity to require the patients to be put to bed. After careful inquiry, it was found that the food had been both simple and nutritious, and reasoning by exclusion, the milk was thought to be at fault.

A mixed specimen was carefully bottled at the dairy, and sent to the Health Department for microscopic examination. The supply was ordered to be discontinued until favorably reported upon. Meanwhile there were no further interruptions in the good health of the inmates in the institution.

The writer, accompanied by Dr. Cornelius, Veterinarian to the Health Department, visited the herd supplying the milk, and found one of the cows suffering from a swollen udder. The dairyman thought that it had been bruised by one of the neighboring cows lying on it. The hands of the men employed about the stables were examined and found free from infected wounds. The examination of the affected udder showed a slight abrasion, with marked swelling, tenderness, and elevation of temperature. The teat was well cleaned, and a thick, yellowish fluid was squeezed from the milk-duct, and caught in a sterile tube. There was no contact between the teat and the tube.

A microscopic examination showed that this fluid consisted almost entirely of pus cells, together with numerous streptococci; and a plate culture in agar gave a pure growth of an organism corresponding in every particular to the streptococcus pyogenes. This organism did not prove virulent when inoculated into a white mouse. Separate mixed specimens were then taken from the milk of each of ten cows of the herd. These were later centrifugalized and stained according to the method described above. The milk of eight cows was found practically free from pus, but the mixed specimen from the entire herd contained many pus cells and streptococci, and the milk from two of the cows contained an average amount of about 10 to 20 pus cells to the microscopic field.

The owner of the herd showed a commendable willingness to co-operate with the Department, and these two cows, together with the first diseased cow, were removed from the stables. An examination of this same stable, made one week later, from the separate specimens from eleven cows, showed that their milk was free from pus, and a second examination made at the end of another week, showed that the milk from the entire herd was practically free from any purulent material.

From the experience above narrated, we thought it probable that the milk from many individual cows must contain varying numbers of pus-cells. We next undertook a series of investigations in order to arrive at a definite conclusion concerning the number of cows practically free from pus, and the varying number of pus cells present in the milk of cows kept under different conditions. After carefully washing the teats, the first milking from each of the four teats was drawn into a sterile tube. While still fresh,

the milk was examined according to the method described above. The averages are all based upon counts of ten microscopic fields with the one-twelfth-inch oil immersion lens and represent the average number of pus-cells in each field. The summary below will show at a glance the difference between cows kept under varying circumstances. They are graded according to the following conditions:

No. 1 consists of one hundred cows in the country, kept in a well-ventilated stable with good roomy stalls, and good pasturage. They are fed while in the stable on bran, ground corn, and hay. The cows are curried and cleansed daily. The herds are inspected by competent veterinary surgeons, and all sick animals are isolated. The usual precautions regarding cleanly milking are observed.

No. 2 consists of fifty cows in the country having badly ventilated stables, narrow stalls, and bad pasturage. They are fed on distillery grains, cut hay, and bran, the precautions mentioned above as regards inspection and cleanly milking not being observed.

No. 3 consists of one hundred cows kept in the city, always confined to stables, with narrow stalls, no ventilation, light, or pasturage. They are fed on brewery grain, distillery slops, bran, and hay. The cows, as a rule, never leave the stable until they go dry or are taken out to be exchanged. The milk was furnished by the city veterinarian, Dr. George C. Cornelius, who was careful to select different sections of the city, and who personally superintended the drawing of the milk. A summary of the results of the examinations of the three grades is as follows:

Grade No. 1 gave a general average of 1.1 pus cells to the field.

No. 2 gave an average of 11.3, while No. 3 showed 19.2. In herd No. 1, practically no pus organisms such as streptococci or staphylococci were found. Herd No. 3 showed streptococci present in large numbers by cover slip in eight instances. The regular nucleus of the epithelial cell enabled us to exclude these bodies in our counts. The milks mixed from the various herds of grade No. 3 showed streptococci, other bacteria and pus. The highest number of pus cells in any one cow was 158.5 to the field. The lowest in grade No. 3 was .1, and there were only 5 which gave this percentage, while in grade No. 1 there were 45. Seventy-five cows gave an average in grade No. 1 of less than one cell to the field, while in grade No. 3, out of 100 cows, there were 12; 93 cows out of 100 in grade No. 1 gave less than 5 cells to the field, while in grade No. 3, 38 gave this average; 98 cows out of 100 in grade No. 1, gave less than 10 cells to the field; in grade No. 3, 54 out of 100 showed this number.

Conclusions.—Garget, or inflammation of the ud-

der and teats, is a not infrequent condition among the many herds supplying milk to various cities or communities.

Milk from such animals often contains many pus cells, and the accompanying organisms of suppuration.

The study of the epidemic just described, as well as the important work of Booker and others, certainly strongly suggests that such milk is capable of causing the various forms of gastro-enteritis, especially in children and infants.

The microscopic examination of the centrifugalized sediment of the milk from a herd of cattle if found to contain an excessive amount of pus, should suggest a careful inspection of the herd.

The chance of infection from drinking milk from a large herd can be lessened by making a microscopic examination of the centrifugalized specimen from each cow, and by the exclusion of such cows from the herd as may be found to contain an excessive amount of pus in their milk.

The standard for exclusion must of necessity be arbitrary, but following the method above described, an average of more than five pus cells to the field of the oil immersion lens should exclude an animal from the herd.

Our results lead us to the conclusion that cows kept in the country, under the conditions noted in regard to grade No. 1, will furnish milk less capable of causing disease than the milk furnished by grades No. 2 and No. 3.

In Baltimore, a city of 500,000 inhabitants, there were 412 deaths from cholera infantum during the year of 1896. This disease is more prevalent among children using cows' milk. We believe that proper legislation looking to the examination of dairy herds and the supervision of dairy stables in the entire State would prevent many deaths from the various intestinal inflammatory diseases. Such legislation seems already practically embodied in "An ordinance to better protect the public health," approved by the Mayor of Baltimore, April 21, 1896, and which might be applied to the entire State.

We would respectfully suggest that the proper food be more clearly stated, and that distillery slop and brewery grains be prohibited as an exclusive diet. It is not claimed that milk which has not undergone such tests will necessarily cause disease, but certainly the adoption of such measures will tend toward securing a purer milk supply and lessening the danger of disease through infected milk. We are indebted to Dr. James F. McShane, Commissioner of Health, for his valuable advice, and the interest which he has shown in our work.

CLINICAL MEMORANDUM.

TUMOR OF THE SPINAL PIA, FIRST CERVICAL SEGMENT, MISTAKEN FOR HYPERTROPHIC CERVICAL PACHYMEINGITIS.¹

By JOSEPH COLLINS, M.D.,

OF NEW YORK;

NEUROLOGIST TO THE CITY HOSPITAL; ATTENDING PHYSICIAN TO ST. MARK'S HOSPITAL;

AND

GEORGE W. BLANCHARD, M.D.,

OF NEW YORK;

RESIDENT PATHOLOGIST TO THE CITY HOSPITAL.

THE symptomatology of intraspinal tumors, whether they be of the dura, the pia, or the medulla, is not so definite and unvarying that the recording of such an occurrence, with a description of the location and confines of the lesion, should not be of deep interest to every physician. In the following history there are many hiatus, but we shall endeavor to make it serve as a text for a few remarks concerning the differential diagnosis of tumor of the spinal meninges and of the cord and hypertrophic cervical pachymeningitis, for which this case was mistaken by the physician who saw him when the symptoms of the neoplasm were well developed.

C. L., a single man, thirty-six years old, of intemperate habits, was admitted to the City Hospital on February 5, 1896. He was said to have had rickets when a child. About twenty years ago, that is, in his seventeenth year, he contracted a chancre, which was followed by the usual secondary manifestations of syphilis. Treatment for the syphilis was carried on only while there were external syphilitic manifestations. Until the present illness he had been quite well. Nine months before entering the hospital he complained of pain in the back of the neck. This gradually crept toward the front of the neck and implicated the right side of the face. The pain at first was sharp and lancinating, but after a few months its character changed, and it became lancinating only at intervals; in other words, the pain, although continuous, became paroxysmal. At this time the patient was unable to move his head readily. He assured us that this spasticity or rigidity of the neck occurred in attacks, and that these coincided with the paroxysms of pain. After a month, or longer, that is, about four months before coming under observation, the head and neck became fixed.

Two months before he came to the hospital he remarked that he was losing the strength of the left arm, and he complained of paroxysmal pains in this region. Upon admission, he complained of being extremely nervous, that he could neither sleep nor eat, that he suffered pain in the back of the neck and head and in the left upper extremity, that the left side of the body was becoming feeble, and that he was growing weaker day by day.

The following conditions were noted in the examination made when he was admitted: The patient maintained the cephalic extremity in a fixed position, and when he turned to the right or to the left the entire body rotated. The left side of the body, particularly the left hand, was weaker

¹ Read before the New York Neurological Society, June 1, 1897.

than the right. The knee-jerk of the left side was much exaggerated, and the triceps and wrist reflexes of the same side were lively and exaggerated. When the patient walked he dragged the left foot and progressed with a swaying movement of the body—a slightly hemiplegic gait. There was no muscular atrophy nor any deformity.

The strength of the left upper extremity became progressively impaired, and he soon was unable to use it. The left hand assumed a slightly flexed condition, but not the "claw-hand" shape. There was no impairment of the sphincters up to this time. The bowels had been very constipated. On May 7th a diarrhea set in, which lasted until the time of his death, a month later, and which was not influenced in the slightest by treatment. Shortly after the onset of the diarrhea there was persistent incontinence of feces. The vesical sphincter did its duty until near the close of life.

The patient made pretty continual complaint of severe pains in the neck and both upper extremities and, later, of pain extending into the legs. As the disease pro-

FIG. 1.

Longitudinal section of spinal column, showing relative position and size of tumor.

gressed, the rigidity of the neck became less, the left upper extremity, which was in a state of beginning contracture when he was first examined, was almost flaccid, and all the extremities became relaxed, yet, withal, the deep reflexes, the knee-jerks, and the elbow-jerks on both sides were very much exaggerated. Whether or not the state of sensory conductivity was investigated cannot be stated, as there is no record regarding it. On February 2d the diagnosis of pachymeningitis cervicalis hypertrophica was entered on the record. The patient continued to complain bitterly of pain, and about a week before his death, on June 8th, he became delirious, and remained so to the end. An autopsy was made a few hours after death. The spinal canal was laid open from the base of the skull to the sacral region. Nothing noteworthy was encountered until the spinal pia came into

view. This was seen to be distended and glistening. On puncturing it over the dorsal region, a quantity of clear cerebrospinal fluid escaped, and the pia then lost the distended appearance. On the posterior surface of the pia, beginning with the first dorsal segment, small white patches or flecks were seen scattered irregularly down as far as the lumbar region. On examination they were found to be calcareous. The pia was neither thickened nor adherent, and the dura was glistening and translucent. The cord itself did not present any abnormality as it lay in the spinal canal, and the cervical region was equally free from disease, as thus seen, as any other portion of the cord. The cord was then left *in situ* and the cranium opened.

The skull was of usual thickness. The veins of the diploë were somewhat congested. The membranes of the brain were of normal appearance. There was no excess of intermeningeal fluid, and the brain itself appeared normal. The encephalon and the spinal cord being completely exposed, a tumor was found lying on the posterior surface of the cervical cord, reaching from the lower border of the oblongata as far as the second cervical segment. The tumor was of the pia, but lay immediately against the cord substance, and measured 3.2 cm. in length, 2 cm. at the widest part, and 1½ cm. at the narrowest end, which was directed upward. The tumor projected slightly into the foramen magnum, but did not exert any pressure at this level. The encroachment upon the spinal cord seemed to begin about half a centimeter below the oblongata-cervical junction. Further examination of the brain failed to show any deviations from the normal.

The *post-mortem* examination of the body revealed an extensive pyelitis of the right kidney, a similar condition, though less marked, of the left, and a very pronounced hypertrophy of the bladder walls. The liver showed interstitial changes, and the apices of the lungs beginning tuberculous involvement. No changes were found in the intestines which would account for the diarrhea from which the patient suffered during the last few weeks of his life. The extremities were in a relaxed state, and careful measurements made at this time showed no difference in the size of the two sides.

On macroscopic examination of the tumor in the recent state, it had the appearance of a sarcoma, or gliosarcoma. It was of a dark reddish color, and was very firm to the touch. It was hardened in alcohol, the cord being placed in Müller's fluid. Microscopic examination of the tumor showed its essential structure to be that of a spindle-cell sarcoma with relatively enormous blood-vessels, some of which, especially the smaller ones, were occluded with hyalin material. Here and there throughout the tumor were signs of recent small hemorrhages, indicating the rupture of the smaller degenerated vessels. In the environment of the vessels which showed most profound degeneration large foci of cheesy degeneration were found.

Examination of the cervical cord, hardened in Müller's fluid and stained with hematoxylin according to Weigert's method, showed that the compression to which the cord had been subjected had largely expended itself on the

crossed pyramidal tracts, in which it had caused descending degeneration of a mild nature, and on the columns of Burdach, which showed an ascending degeneration of a degree even milder than that in the pyramidal tract. Aside from the change in the contour of the cord, insignificant vascular changes, and what appeared to be a slight degree of perivascularitis in the ventral horns, the cord was normal. To recapitulate briefly, the symptoms in this case were:

1. Pain, at the onset, in the back of the neck, later extending into the side of the face, and into the upper extremities, and later yet into the lower extremities.
2. In the beginning the pain was continuous, and of a dull, irritating character; later it occurred paroxysmally, and was of a lancinating nature.
3. A feeling of tension and spasticity in the cephalic extremity, and to a lesser degree, in the upper extremities, more particularly in the left arm.

some symptoms were lacking, the appearance of which one should perhaps always await before consenting to make a diagnosis of hypertrophic cervical pachymeningitis. The occurrence of the symptoms of the latter affection fall into two distinct periods or epochs, corresponding to well-defined anatomic conditions. These are, first, a period of pain and rigidity of the muscles of the cephalic and upper extremities which indicates encroachment of the pathologic process upon the spinal roots, particularly the posterior, and, second, the period of paralysis, contracture, atrophy, and deformity, particularly of the upper extremities, which correspond to the implication of the substance of the cord by the morbid condition and degenerative changes of a secondary nature in the peripheral nerves.

The pain of cervical pachymeningitis is not unlike that complained of by the patient in this instance. It is located at the outset in the back of the neck, but soon

FIG. 2.

Cervical cord at the level of the third cervical nerve, showing degeneration of the pyramidal tracts and column of Goll.

4. Progressive loss of strength in the left upper extremity, and to a lesser degree, in the left lower extremity.
5. Exaggeration of the deep reflexes. In the beginning this exaggeration was of the left side alone, but later increased myotatic irritability was universal.
6. Progressive flaccidity of the parts which had previously shown a state of tension or spasticity.
7. Progressive and uncontrollable diarrhea.
8. Symptoms referable to deranged intracranial circulation, pressure, and delirium.

If we contrast these with the symptom complex, which Charcot and Joffroy first claimed was sufficiently characteristic and constant of a form of cervical pachymeningitis to entitle it to individual classification, we shall see that although the symptoms, which the patient had, belong to the complex of symptoms constituting the latter disease,

extends toward the front, and to the sides of the face. Later, the large joints of the upper extremities often are the points to which the intensest suffering is referred. At the outset, this pain is continuous, but after a few months or less it occurs in paroxysms. The rigidity of the upper part of the body and the paresthesia which occur at this time remind one of cervical caries.

Until other symptoms develop, it is impossible to make a positive diagnosis. The paralysis and atrophy of the muscles which follow and the deformity are considered to be quite typical. The paralysis of the upper extremities and the atrophy is mainly in the domain of the ulnar and median nerves. This atrophy causes the development of the "claw-hand," which is perhaps the most constant feature of cervical pachymeningitis. It is the immediate result of flexion of the fingers, due to paralysis or degeneration of the median nerve, and extension of the wrist,

on account of the ulnar-nerve disability, the action of the posterior interosseous being unopposed. Atrophy of the muscles of the upper extremities may be very extensive and the spasticity and fixation of the joints be as pronounced as in a case of amyotrophic lateral sclerosis. The disturbances of sensibility are not constant and vary with the degree of encroachment made by the morbid process on the dorsal surface of the cord and the posterior roots. Some degree of sensory disturbance is always present. The occurrence of other symptoms with hypertrophic cervical pachymeningitis points to secondary changes in the cord due to implication of the descending tracts, principally, and are those of a more or less diffused myelitis.

In the case here reported, then, it would appear that there were lacking symptoms that should be present to warrant a diagnosis of cervical hypertrophic pachymeningitis. Moreover, the course of the disease, the unfolding of the symptoms, and especially the irradiation, the character and intensity of the pain, should have suggested the possibility of intraspinal tumor. It is unfortunate that no record was made of the sensory disturbances, as it would count for much in favor of a tumor if the distribution of some form of anesthesia had been present with anything approaching regularity.

The question of the symptomatology of intraspinal tumors is to-day a very legitimate subject for debate. There would seem to be nothing like unanimity among different writers as to what constitutes the symptomatology of growths situated within the spinal canal. As a matter of fact, when it is said that the symptoms depend very largely upon the position occupied by the tumor, to a less extent upon the location, and to a comparatively slight degree upon the size and nature of the growth, all is said that can be stated truthfully. We have become so accustomed to a moderately unvarying symptom complex resulting from intracranial growths, and which, so far as we know, is dependent upon a perversion of intracranial pressure, that unthinkingly we believe that something similar should be present in the case of intraspinal tumor. As a matter of truth, there is not. Intraspinal pressure counts for very little or nothing, and this because of the entirely different interrelationships between the coverings of the cord, constituting the important lymph spaces, and those existing between the brain and its coverings.

It seems to me a matter of sufficient importance to deserve especial attention that oftentimes motor symptoms are principally root symptoms, even until late in the course of the disease. Before they cause cord symptoms, death usually overtakes the patient, unless the tumor is of the cord itself, or unless it is a tumor that grows rapidly and thus causes early spinal-cord implication. In the case reported, the root symptoms dominated until the end, and the symptoms were never of such a nature that it could be said that the substance of the cord itself was involved. The obstinate diarrhea from which the patient suffered was, I venture to believe, a symptom referable to the sympathetic system, and was caused by implication of sympathetic fibers entering with the posterior roots. Whether or not there were other sympathetic vegetative

symptoms I cannot say, as the patient did not come under our observation until a few days before his death, when he was in a state of profound collapse, and no notes had been made of such conditions in the case-book.

It would be easy to theorize on the relationship of the disease of the urinary organs to the sympathetic system and to the cervical cord, but I prefer merely to record its occurrence.

MEDICAL PROGRESS.

The Bacterium Coli in the Urinary Passages.—The presence of the bacterium coli in the urinary passages according to MELCHOIR (*Centralbl. für d. Krankh. d. Harn. und Sexual-Organen*, vol. viii, p. 242) is responsible for most cases of infection of the bladder, and also for most cases of pyelitis, pyelonephritis, and nephritic abscess. These affections are not to be regarded as separate disorders, but as results of one common cause—the infection locating itself according to circumstances in one or the other portion of the urinary tract. These views are not those of the writer alone, but are shared by numerous others whose published opinions are quoted by him.

GRAF (*Deut. Med. Woch.*, No. 38, 1896) examined, bacteriologically, two cases of pyelonephritis and found in one the bacterium coli and in the other a bacillus similar to this. The origin of these bacilli was not evident, nor could Graf determine the route by which they reached the kidney.

"Bi-Polar Pressure" in Cases of Doubtful Fracture.—A writer in *La Presse Medicale*, May 15, 1897, calls attention to a means of differentiating between contusions and fractures—a point which, by the way, must have occurred to many others. As the pain in contusions may be very great, it is desirable to distinguish this pain from that caused by a break in the bone. If lateral pressure is made this cannot always be done, but, on the other hand, if pressure is applied at the ends of the bone—on elbow and shoulder in case of the humerus—pain will be present in fracture and absent in contusion. This method of examination is spoken of as "bi-polar" pressure.

Albuminuria of Delirium Tremens.—LIEPMANN (*Arch. für Psych.*, etc., 1896, vol. 28, No. 2) examined seventy-two patients suffering from delirium tremens, of whom fifty-six, or seventy-six per cent., had albuminuria, which, in forty cases, was only transitory. In sixteen cases the albuminuria appeared to be permanent. Seven of these patients died; five of them had nephritis, but the cause of the albuminuria in the other two was not evident.

The most important symptom, as an index of the delirium, was the pulse, which increased with commencing mental disturbance, and fell when the brain began to clear. In most cases there was no fever. Usually the albuminuria rose and fell with the pulse, and the delirium had no connection with the fever. The degree and kind of delirium was not different in those cases without albuminuria than in those in which it was present.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	\$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JULY 3, 1897.

WHEN MAY A SYPHILITIC MARRY?

THE earliest date after infection at which a syphilitic may marry without danger of communicating syphilis directly or by heredity is gradually being advanced by those who have carefully studied the subject. Some years ago Fournier and Besnier said that an individual properly treated might marry with impunity four years after the initial lesion. Recently Besnier has extended the time to five years. Even this long period seems too short in some instances. Thus, Morel-Lavallee, in the *Rev. de Therapeut. Med.-Chirurg.*, November 15, 1896, has collected from the literature thirty-seven cases, to which he adds a thirty-eighth, in all of which infection took place more than five years after the initial lesion. In all of these the contagion was spread from a so-called secondary lesion.

Perhaps the most remarkable paper recently published on this subject is that of Tarnowski, which was read before the last Congress of Dermatology held in London. Of 1000 cases of syphilis which were under observation for more than five years, all exhibited condylomatous lesions for three years or more, while 802 exceeded that period by two years.

No less than 200 (twenty per cent.) showed "secondary" symptoms after five years, and in 31 cases there were secondary lesions after ten years. It ought, therefore, according to Morel-Lavallee, to be the invariable rule to allow at least five years to elapse before marriage; but this should not take place even then until a year has passed since the disappearance of secondary symptoms in a person not given to recurrence of mucous plaques or erosions of the lips or tongue.

A NEW SPECIFIC FOR TUBERCULOSIS.

THE report of a new treatment of pulmonary tuberculosis by a modified tuberculin elaborated by Hirschfelder at San Francisco, which was published in the last number of THE MEDICAL NEWS, will doubtless attract considerable attention from clinicians and pathologists.

From its pathologic standpoint the article gains consideration as presenting the results of carefully conducted laboratory experiments. That the tubercle bacillus should be destroyed by the action of its own product slightly altered, as by oxidation, is not at all improbable but rather in line with some well known observations in bacteriology. Such a view is, however, not in accord with the generally accepted opinion that specific immunity is the result of an entirely new substance different from the bacterial toxins and produced in the organism as a secondary result of the action of these toxins and bacteria. Proceeding on this basis Koch has been laboring for years in the endeavor to so thoroughly distribute the tubercle bacillus throughout the organism as to excite the production of this immunizing agent by natural processes, claiming that in no other way can the antitoxin of tuberculosis be secured in sufficient concentration for use in therapeutics.

That by simply heating tuberculin with peroxid of hydrogen a product should be obtained identical with that resulting from very complex metabolic processes in the animal organism is not impossible but seems almost too simple to be true. As a rule albuminous principles treated chemically in the test-tube do not correspond in action to closely related principles isolated directly from the animal body, and it seems probable that if the antitoxin of tuberculosis is to be manufactured it must be done in the animal body rather than in the thermostat.

As for the premises on which Hirschfelder proceeds, it is of little moment to point out that simple access of air is almost certainly not the essential curative agent in successful operations for tuberculous peritonitis. It may be suggested also that the prolonged heating of tuberculin with peroxid of hydrogen may very well produce, in the toxin, other changes than oxidation.

An examination of the results obtained by the treatment shows much information to be desired. A New York physician would send a patient falling in Hirschfelder's first class to California with a good prognosis as to recovery within a year. Many such results are seen at Saranac. The exact conditions under which these patients were treated are therefore essential data in judging of the efficacy of the special treatment. Further, if oxytuberculin is the anti-toxin of tuberculosis, we should like to know the efficacy of this agent in limiting the course of tuberculosis in inoculated guinea-pigs. The lack of evidence from experimental pathology will especially strike those best fitted to judge of the probable value of the remedy, *viz.*, experimental pathologists.

But whatever fears may arise as to the ultimate fate of the new treatment, it cannot be classed with the host of ephemeral specifics constantly being thrust upon the profession. Hirschfelder's work bears the stamp of careful and competent study on a distinctly scientific basis, and whether ultimately successful or not, the investigator's claims seem to deserve the consideration of the medical public.

ECHOES AND NEWS.

Pauper Centenarian Dead.—The Coroners' Office was recently notified of the death from consumption of a female inmate of the Almshouse on Blackwell's Island. The woman was 105 years old.

French Congress of Surgery, 1897.—The eleventh session of the French Congress of Surgery will commence in Paris on October 18, 1897. The following subjects will be discussed: (1) "Contusions of the Abdomen;" (2) "The Indications for Operation and the Treatment of Cancer of the Rectum."

Death of Dr. William C. Wey.—Dr. William C. Wey died of apoplexy on June 30th at his home in Elmira, N. Y. He was born in Catskill, N. Y., in 1829, and graduated at the Albany Medical College in 1849. He was President of the State Medical Society in 1871, and for many years was Health Officer of Elmira.

Nail Fired into His Tongue.—A young man of Saugerties, N. Y., recently made use of a wire nail to dislodge a cartridge from a revolver. While he was thus engaged, the revolver was discharged and he received the full charge in his face. Later the nail, which measured three and one quarter inches, was found embedded diagonally across the tongue.

Special Instruction for Feeble-Minded Children.—A report on the district schools of London brings out the fact that about one per cent. of children of school age are so far below the normal in physical and mental power as to require special training. A separate class-room is to be allotted to these children, where they will receive a modified kindergarten training and suitable physical exercise.

Pilgrims and Quarantine.—The *Lancet* says that at Mecca "pilgrim diarrhea" has become an annual factor which has never yet been dealt with, and there is even a suspicion that for the last few years cholera has been endemic there. As Turkey has, up to the present time, done nothing in the matter, it is suggested that Europe insist that these pilgrimages be conducted on cleanly and decent lines.

To Sue for His Medical Diploma.—It is said that a colored student of the Rush Medical College, Chicago, has begun suit in the Circuit Court for a writ of mandamus compelling the college authorities to issue to him a diploma. The student claims that the diploma was withheld on the charge that he had copied answers from other students in the course of his final examination. This he denies, and demands proof of the charges or the granting of a diploma.

Cremation of Garbage.—The village of New Brighton, S. I., has been greatly exercised over the question of the disposal of garbage. A crematory was built in which the garbage was burned, but some of the residents in its immediate vicinity protested against the bad odors. An injunction was granted prohibiting the use of the crematory, but, upon it being shown that the bad odors were due to faulty working of the plant, the latter was remedied and the injunction removed.

Blindness Caused by Drinking Essence of Peppermint.—The news comes from Washington, D. C., that a Wisconsin Indian Agent has reported two peculiar cases of blindness occurring on the Vermillion Lake Reservation. Two Indians drank essence of peppermint as a substitute for whisky, one taking almost ten ounces clear, and in each case blindness followed within a few hours. A case was recently reported in Philadelphia in which blindness occurred after drinking a quantity of Jamaica ginger.

New York State Board of Health.—A meeting of the State Board of Health was held in New York City on June 29th. A communication from Attorney-General Hancock advised the Board that it has the right to take such steps as it sees fit, independent of any opposition that may be offered, to abate nuisances which have been complained of. The report of the sanitary condition of the State announces that a decrease of 1,000 deaths over the cor-

responding period for the previous month has been reported.

Tornado Neurosis.—The people of St. Louis are suffering from a new disease called tornado neurosis. According to a physician in that city, women and little children die from time to time as a result of the nervous shock caused by the tornado of a year ago, and the repeated shocks caused by the alarm which they experience whenever there is a thunder-shower. The latter is largely due to sensational newspapers which publish greatly exaggerated bulletins whenever a storm is predicted by the Weather Bureau.

Haffkine's Plague Prophylactic.—The results of Professor Haffkine's inoculations against the bubonic plague in India afford a striking instance of the value of antitoxic methods of prophylaxis. It is indeed remarkable that the introduction into the body of the mixture which results from the growth of the plague bacillus in a mass chemically so complicated as a mixture of native "ghee" and bouillon should cause the inoculated to suffer about twenty times less than the non-inoculated, living under the same conditions and exposed to the same infection.

Not Necessary to Die.—Dr. C. A. Stephens, of the Boston University Medical School, is reported as saying he is convinced that the progress of brain science will enable mankind to successfully overcome decay and its climax—death. He further states his belief that death at seventy years or thereabouts is due to the fact that generation after generation is born into the world expecting to die at that time and therefore die. He expresses the opinion that if children were brought up to believe they would live forever, the life limit would gradually be extended in the course of several generations.

The Wearing of Clothing Disastrous to the Savage.—A writer in *Harper's Magazine* claims that civilization will rapidly exterminate the savage races. The first thing done for the black heathen is to make him wear uncomfortable clothing, in which he sweats and breeds poisonous microbes with horrible fluency. He never changes his clothing, and when he gets wet he knows no better than to dry it by sitting close to a fire. In this way he contracts fever, which undermines an otherwise robust constitution. The so-called Christian natives disappear rapidly after being clothed in the armor of civilization.

The Lancet and the Jubilee.—*The Lancet*, which was founded fourteen years before Victoria ascended the throne, gives in the issue of June 19th a brief résumé of the advances made in medicine during her reign. In the chapter on surgery credit is given America for the discovery of ether. Knight of New Haven, is mentioned as having in 1848 employed digital compression in cases of aneurism. Weir Mitchell is referred to as having been the first to perform suture of nerves. Halsted's operation for the cure of inguinal hernia is mentioned, and credit given Marion Sims for removing a gall-stone from the cystic duct in 1878.

Horseless Carriages for Doctors.—Dr. Charles C. Booth of Youngstown, Ohio, seems to deserve the distinction of

being the first physician in this country to adopt a horseless carriage for use in his practice. The doctor is inventive, and has devised what he calls a motor cab, which he has used for several months. The cab is capable of making a speed of ten miles an hour on a level, and will climb a grade of from ten to fifteen feet to the hundred at the rate of five miles an hour. It seems that in sections of the country where the roads are uniformly good physicians will soon be able to do away with the expense of keeping horses, and will rely upon bicycles or horseless carriages.

Pills Under the Hammer.—In a recent article with this title in the *Pharmaceutical Era*, Dr. Windolph says: "'Lead pills' have their place in military warfare; but the physician in battling with disease should select his ammunition for other qualities. I make no comment on the solubility of a pill, whether coated or uncoated, which is of sufficient hardness to penetrate a pine board. I feel justified, however, as a pharmacist, in contending that the interests of the physician, the patient, and druggist as well, are better served by pills extemporaneously prepared, or, in any event, by the use of such manufactured pills as are known to be in a permanently soluble condition."

Physiologic Testing of Drugs.—The physiologic activity of medicinal agents is just now receiving much attention from physicians, and methods have been devised whereby it can be directly tested, entirely apart from chemical analysis. In the near future pharmacists may be required to guarantee not only that the drugs they sell are pure, but that they possess the required ability to act on the systems of those to whom they may be administered. *The Pharmaceutical Era* says: "It is well known among investigators that there are certain classes of remedies which cannot be standardized by any chemical means. Some of these remedies are the most important in the whole Pharmacopeia. The group of heart tonics is perhaps the most notable, including as it does a very large number of drugs that are constantly prescribed by the physician. Of this group of heart tonics, undoubtedly digitalis is the most important."

Health and Population.—Some official figures recently appeared in London which gave great surprise to social economists. They were filed with the registrar-general, and showed that the death-rate was relatively lower in the larger cities of England than in the small ones. The rate in London was 15.5 per 1000 inhabitants; in Liverpool, 19.9; in Hull, 15.8, and in Sheffield, 19.1; but in the town of Plymouth it was 23.5; in Salford, a suburb of Manchester, 25.9; in Bolton, 25.8, and in Burnley, 25.1. Though the sanitation of large cities is, in the main, better than that in the smaller towns, the transient population is larger in the former and, moreover, the big cities usually maintain a larger number of public, penal, and charitable institutions, hospitals, asylums, and prisons, which add materially to the death-rate. In the city of New York, for instance, as the last figures of the Board of Health show, nearly 10 per cent. if, indeed, not quite

10 per cent., of the interments are pauper burials made at the public expense and from public institutions usually.

New Appointments and Changes in Bellevue's Faculty.—

The following new appointments have been made in the Faculty of Bellevue: Dr. Charles L. Dana, Professor of Diseases of the Nervous System; Dr. Henry C. Coe, Clinical Professor of Gynecology; Dr. Henry H. Rusby, Professor of Materia Medica and Pharmacology; Dr. John A. Mandel, Adjunct Professor of Physiological Chemistry; Dr. William H. Park, Lecturer on Bacteriology and Hygiene; Dr. George D. Stewart, Professor of Anatomy; Dr. Austin Flint, Jr., Professor of Obstetrics and Clinical Midwifery; Dr. Herman M. Biggs, Professor of Therapeutics and Clinical Medicine and Adjunct Professor of Principles and Practice of Medicine. Dr. Joseph D. Bryant has given up the Chair of Anatomy and has been appointed Professor of the Practice of Surgery and of Operative and Clinical Surgery. Dr. Lewis A. Sayre has been made Emeritus Professor of Orthopedic and Clinical Surgery. Dr. Reginald H. Sayre has been appointed Lecturer on Orthopedic Surgery. Dr. Carlos F. McDonald has had the department of Medical Jurisprudence assigned to him in addition to the Professorship of Mental Diseases. Dr. D. Hunter McAlpin, Jr., has been promoted to Professor of Gross Pathology and Clinical Registrar.

Disappearance of Plague from Bombay.—According to the *British Medical Journal*, the epidemic of plague which has raged in Bombay for nearly a year is practically over, although a few new cases will probably be reported during the coming twelve months. But 15,000 deaths are recorded in a population of nearly 800,000—a very low mortality compared with that of the 1666 plague in London, which was estimated at forty per cent. of the entire population. The sanitation of Bombay and the active medical measures taken to prevent the spread of the disease have undoubtedly saved thousands of lives. Apparently nothing will shorten the duration of an epidemic, as is shown by the fact that in Hong Kong, in spite of its almost perfect water supply and modern drainage and sanitary and medical supervision, the plague lasted as long as it did in Canton, where there is absolutely no sanitation whatever. But it is evident that sanitation is of the greatest importance in limiting the number of persons attacked during an epidemic, and that improved sanitation is the weapon by which the dread scourge should be fought. The following essential points should be borne in mind in the event of plague becoming epidemic in any civilized community: First, that there is no such thing as a mild outbreak of true bubonic plague. Second, that private interests must stand aside for the time being, and that full powers must be granted to a supreme body to deal with all sanitary measures in the manner which seems best calculated to lessen the number of persons attacked.

The Jubilee Number of the British Medical Journal.—In commemoration of the Queen's Jubilee, the *British Medical Journal* issued June 19th a very large number which

is entirely devoted to a detailed record of the progress of the medical sciences during the Victorian period. The review is illustrated by seventy-five cuts, one of which is a portrait of Marion Sims, the only American thus honored. After mentioning as main factors in the advance of medicine, the invention of instruments of precision, the discovery of causes of disease, improvement in the means of preventing disease, simplification of treatment, antitoxins and organic extracts, anesthesia, and antisepsis, an exhaustive review is given of the progress of every department of medicine during the past sixty years. Much prominence is given to the work done by subjects of the Queen, although occasional mention is made of that done by Americans. In the section on obstetrics mention is made of observations in America concerning contracted pelvis and difficult labor. In that on gynecology special mention is made of the Johns Hopkins Hospital and of Howard Kelly and his staff; Marion Sims and Bozeman are spoken of in connection with operations for the repair of lacerations of the perineum and for vesico-vaginal fistula; Emmet's operation of trachelorrhaphy is also mentioned; Ephraim McDowell is the only American mentioned in the chapter on abdominal surgery. The Weir-Mitchell treatment of neuroses is referred to. In the article on anesthesia, no mention is made of Morton as the discoverer of ether.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

A LAW FOR THE INSPECTIONS OF BAKERIES—THE SUMMER EXODUS OF PHILADELPHIA MEDICAL MEN—BLOCKLEY NOTES—DR. J. M. DA COSTA—AN OBNOXIOUS PIECE OF LEGISLATION—VITAL STATISTICS FOR THE PAST WEEK.

PHILADELPHIA, July 3, 1897.

ALTHOUGH the butcher must submit the meat he intends selling to a close inspection before he may dispose of it, and the dairyman is compelled to submit his products to official surveillance before they reach the consumer, the baker and the confectioner, until the passage of the present Bake-Shop Law, which officially went into effect a few days ago, have always managed to evade a close inspection of their methods of manufacture by the authorities. But this large class of manufacturers will now be compelled to comply with regulations which have for a long time governed other producers of food-stuffs, and to serve the public with a product whose purity and cleanliness in preparation is approved by the inspectors of the State Factory Department.

The new Bake-Shop Law proves to be a most sweeping—and, if properly enforced, will be a most valuable—act of legislation, and its literal application will result in the reconstruction of hundreds of bakeries throughout the city and the closing up of many more. It includes in its jurisdiction bread bakeries, confectioneries, macaroni factories, and pretzel and pie bakeries; regulates the hours for employes, and forbids the employment of all but healthy persons; it also provides for the proper ventila-

tion, drainage, and plumbing of all buildings and rooms in which the manufacture of this sort of food is carried on.

No one who has not investigated this matter personally can have any conception of the unsanitary condition of many of the bakeries in the poorer sections of this city, and it was high time that a law was passed by which these foci of disease and filth may be eliminated. It will be interesting to watch the practical application of this measure, with its ins and outs of political complexities; but it is to be hoped that the enforcement will be thorough, and the results a gain in the sanitary condition of the community.

The summer exodus has begun in earnest, judging from the boarded-up fronts which the offices of many prominent medical men present and from the numberless signs of "Patients are referred to Dr. So-and-So until September 1st" which one sees at every turn. The stay-at-home laity, in some sections of the city, keep their doctor with them the whole year round; but to hunt for your physician, should he happen to live in the center of town, would be, in many instances, a disappointing and hopeless endeavor. Dr. James C. Wilson has gone to Rye Beach, N. H., for the month of July, and intends to pass the remainder of the summer in the Maritime Provinces of Canada. Dr. Edward Willard Watson is at Castine, Me., where he will spend this month and next. Dr. Edward P. Davis is at Marion, Mass., for the rest of the summer. Dr. Henry C. Chapman, Dr. John B. Shober, and Dr. S. Madison Taylor are spending the season, as usual, at Bar Harbor, Me. Dr. Thomas G. Morton has taken a cottage at Cape May, N. J., for the season. Dr. Thomas G. Ashton will spend the summer at Atlantic City, N. J. Among the recent departures for Europe may be mentioned Dr. Arthur V. Meigs, Dr. Charles P. Noble, Dr. John H. Packard, Dr. P. S. Donnellan, and Dr. Horace Y. Evans. Dr. William W. Keen leaves the latter part of July for an extended trip through the Northwest, including Alaska. Dr. William G. Porter will spend August at his country house at Fairfield, Conn.

The daily population at the Philadelphia Hospital (Blockley) for the past year averaged 3494 persons in all the departments of the institution. The insane department showed the greatest gain in patients, having cared for 830 more cases daily in 1896 than were treated ten years ago, an increase of 210 per cent. A curious phase of the Department of Charities and Correction, the administrative body governing Blockley, may be found in the *personnel* of the Out-door Staff of district physicians, which is so composed that the discriminating poor may choose for gratuitous medical attendance at their homes either a regular practitioner or a homeopath, depending upon the patient's individual mark of intelligence. The announcement that twenty-five of these medical make-shifts have been added to the out-door service would appear to indicate their popularity with the lower classes; but it is gratifying to note that this medical tinkering is wholly extramural in character, for all the internes of the hospital are graduates of regular schools of medicine.

At the annual commencement of Harvard University,

held on June 30th, the honorary degree of LL.D. was conferred upon Dr. Jacob M. Da Costa. Dr. Da Costa delivered an oration before the alumni association of Harvard during the meeting of that body this week.

The Board of Health is up in arms against a bill awaiting the Governor's consideration, which proposes to dispense with the present law making marriages returnable to the Health Officer. It is inconceivable what legislative stupidity called into existence this bill, which not only aims to destroy the continuity of the valuable records of marriages, births, and deaths kept for the past twenty-seven years by the Bureau of Vital Statistics, but, should it become a law, would obviously prove a decided obstacle in the settlement of certain legal and social questions which might arise in the future; one occasionally requires proof of one's marriage, and the Board of Health's protest will probably result in the continuance to citizens of Philadelphia of this privilege.

The number of deaths in this city during the week ending July 3d was 492, an increase of 64 over those of the preceding week; of the total, 226 occurred in children under five years of age, cholera infantum causing 58 fatalities. The returns of contagious diseases for the week show a total of 205 new cases, a decrease of 64 from last week; 63 were diphtheria, 99 scarlet fever, and 43 enteric fever; there were 25 deaths from diphtheria, 7 from scarlet fever, and 6 from enteric fever.

OUR VIENNA LETTER.

[From our Special Correspondent.]

OFFICIAL REPORT OF THE AUSTRIAN PLAGUE COMMISSION—ETIOLOGY, CLINICAL FEATURES, TREATMENT AND TRANSMISSION OF THE PLAGUE—FEVER IN LEUKEMIA WITH NO OTHER CAUSE BUT THE BLOOD CONDITION—PROFESSOR MONTI ON THE DIFFERENTIAL DIAGNOSIS OF ANGINAS IN CHILDREN.

VIENNA, June 12, 1897.

THE commission sent by the Austrian Government to Bombay to investigate the etiology, pathology, and clinical features of the pest, returned last week. Its official report was read at the session of the Imperial Academy of Sciences of Vienna on May 20th. As the clinical and pathologic material, through government influence, was entirely in their own hands, the members of the commission were, in the words of the report, "in the pleasant position of absolute independence, and their conclusions are the result entirely of their own observations and experience."

As to etiology, they confirm the generally accepted opinion that the bacillus found and described by Yersin and Kitasato is the cause of the disease. These bacilli may be found in large numbers in all lymphatic tissues, and especially in the spleen. While the disease may be conveyed to animals by direct inoculation, the members of the commission observed its spontaneous development only in rats. Mixed infection plays an important rôle in the severity and variety of the symptoms noted in the course of the disease. All the ordinary microbes seem to find a favorable culture-medium in the blood of affected

persons. The streptococcus, the diplococcus pneumoniae, and the staphylococcus were observed with special frequency. Three types of the disease could be distinctly differentiated, the first being a septicemic hemorrhagic form characterized by septic hemorrhagic buboes, and by hemorrhages in the walls of neighboring venous trunks. This form, by far the most common one, presents a specifically characteristic swelling of the spleen, and specific changes in all the lymphatic tissues, the lymph glands, the intestinal follicles, and the follicles of the mouth, throat, and tonsils. The second form is a septic pyemia, with metastases to the internal organs, especially the lungs, liver, and kidneys. The third form is a primary pest-pneumonia—a specific confluent, lobular pneumonia.

The favorite points of entrance for the infecting material are, in the order of importance; (1) The skin, with consequent lymphatic involvement. This is by far the most frequent mode of entrance. (2) The lungs, occurring in a very much smaller number of cases; and, (3) the tonsils, a very rare form, but of interest as exemplifying the importance of that ever-open road to infection. In these cases the glands beneath the jaws showed the characteristic buboes. No case of infection through the intestinal tract was noted.

Besides the symptoms usually noted, both serum and nuclear albumin were always present in the urine, though in small amounts. The chlorids were always considerably diminished. No blood was found in the urine of any of the patients, and the ophthalmoscope never revealed the presence even in frankly hemorrhagic forms of the disease of hemorrhages into the retina. Slight leucocytosis was noted.

The diagnosis was difficult only when the characteristic buboes were absent, as in the pneumonic form of the disease. The presence of the bacilli in the sputum was then diagnostic. As to treatment, none of the pharmaceutical remedies used seemed to have any effect on the course of the disease. The investigators did not observe the success which has been reported from the use of Yersin's antitoxic serum, though they saw it employed in a number of instances. As to Haffkin's treatment with sterilized cultures of the bacilli, the official report is not so definitely unfavorable. The results of certain experiments and further observations are awaited. In private conversation, however, some members of the commission have expressed themselves as absolutely without confidence of any good resulting from this method of treatment.

As to the danger of the transmission of the pest to other countries, the probability of such an event does not seem at all likely. The plague is not easily carried in fomites, and very ordinary precautions will suffice to prevent its transmission in this way. Under proper medical supervision, which need not be of extraordinary character, the danger of its being transmitted to other countries by affected persons is extremely small. The presence of large numbers of rats on shipboard at all times, and their now thoroughly known liability to the disease makes the coming of ships from parts where the disease is prevalent always a reason for strenuous precautions.

The report of a case of leukemia from Professor Schrötter's clinic here has just been published in which for months before death there had been a daily evening rise of temperature of 2.5° to 3° C. The autopsy made with extreme care by Professor Weichselbaum himself showed no traces of a tuberculous or septic process in the system. Quinin never had any effect on the fever. The other antipyretics seemed only to cause abnormally lowered temperatures when the drop came, but did not lessen the rise. The fever itself seemed to have no effect on the leucocytes.

Professor Schrötter, in a clinic a few days ago, called attention to the fact that besides leukemia, other of the serious blood changes—chlorosis and the severer forms of anemia—were accompanied under certain circumstances by this tendency to temperature disturbances. The explanation would seem to be that a ferment intoxication occurs which is due to the absorption of certain elements not present in the condition of normal blood equilibrium, but liberated when that equilibrium is disturbed—elements which are of great importance in certain conservative processes, as clotting, etc.

Professor Monti, at the Polyclinic, has just concluded a series of lessons on anginas in children. As was to be expected from so well known a clinical teacher, the points given were very practical and were strikingly presented. As to differential diagnosis, of course, the important point is the bacteriologic examination in all cases where there is a membrane present. This requires practically twenty-four hours of time, and meantime treatment must be begun in private practice, for if the case is one of diphtheria valuable time may be lost by delay. The external appearances then have not lost their importance and will usually serve to indicate whether diphtheritic treatment and isolation should be instituted at once. Punctiform patches of membrane on the tonsils usually indicate only infection by staphylococci—a follicular tonsillitis. When the membrane occurs in larger patches, but is limited only to the tonsils, especially if a piece of the membrane removed from the throat is not tough and consistent but crumbles readily between the fingers and does not show a fibrinous network under the microscope, it is streptococcic in origin. The true diphtheria membrane is not so apt to be localized to the tonsils, and owing to its fibrinous character does not crumble easily.

Any membranous affection in the throat of a child calls for isolation, for even in the mild staphylococcic form the microbes have an acquired virulence that makes them contagious for children living under the same conditions, and the lesions they produce make easy points of entrance for diphtheria bacilli.

As to treatment, besides the antitoxin local measures must not be neglected. Gargling is usually out of the question, for even with older children it cannot be practised with sufficient frequency to be of any practical therapeutic value. Sprays are so evanescent in effect that their repetition often enough to be of use would seriously worry the patient, so that the indication seems to be always for the use of powders. These remain long enough in contact with diseased parts to have the desired antiseptic

effect. As all the throat bacilli grow better in an alkaline medium, only acids should be used in the treatment. Boric acid and tannic acid, especially the latter, are the favorites in Monti's children's wards at the Polyclinic. Iodol or iodoform in powder are used in the severer cases. Second attacks of genuine diphtheria Monti considers to be much rarer than is usually thought. Diphtheria leaves a throat in a state of lowered vitality, and staphylococci and streptococci readily find a lodgment in it, but true diphtheria recurs almost as rarely as other children's diseases.

ROENTGEN RAYS WITHOUT GERMICIDAL POWER—THEIR USE IN THE DIAGNOSIS OF DISEASES AFFECTING THE DEVELOPMENT OF THE SKELETON—THE RESULTS OF CALOT'S FORCIBLE REDUCTION OF THE DEFORMITY IN POTT'S DISEASE—IS HYDROCEPHALUS HEREDITARY?—THE TREATMENT OF ACUTE ECZEMA BY PICRIC ACID—CONGENITAL ORIGIN OF MOVABLE KIDNEY—MUSCULAR RHEUMATISM FOLLOWING GONORRHEA—THE EFFECT OF ANTISYPHILITIC TREATMENT UPON TUBERCULOSIS.

At the session of the Academy of Sciences, held May 3, 1897, SABRAZES and RIVIERE stated that *the Roentgen rays have absolutely no effect upon the bacillus prodigiosus*, and the cultures of this bacillus, although exposed to the action of these rays, showed absolutely no change in their chromogenic properties, morphologic characteristics, or vegetability. In frogs exposed to the influence of the rays, the action of the leucocytes was not effected, either as regards their number or phagocytic powers. In some cases there seems to be an increased flow of lymph. Furthermore, a frog's heart is not modified in its rhythm until after an hour's exposure to the rays.

At the session of May 17th, SPRINGER and ŠERBANESCO demonstrated the *advantage of the use of Roentgen rays in the study of different troubles affecting the growth of the skeleton*. A most remarkable fact was furnished by myxedema. In this affection the radiograph showed a persistence of certain infantile conditions, even at the age of thirty-four years. In hereditary syphilis the arrest of development appeared to be due to a premature ossification with persistence of the cartilage. In alcoholic children the cartilage is thin, irregular, and prematurely ossified. In tuberculosis, either hereditary or acquired, the cartilage persists and its ossification is delayed. In short, a number of diseases produce alterations in the epiphysal cartilage and in its method of ossification. In such affections the radiograph gives a new physical sign easily appreciable and most useful for diagnosis. Investigation along this line will also serve as a guide to treatment, for if the cartilaginous zone is opaque all treatment having for its object increase in the growth is useless, as this has been definitely arrested.

At the session of May 12, 1897, BRUN reported to the Society of Surgery that he had performed *redressement brusque upon two patients suffering from Pott's disease with deformity*. In one case the lesion was three and

one-half months old and disappeared under pressure, apparently without the production of such a large anterior cavity as is brought about by this operation upon the cadaver. In the other case the projection had been noticed for five months. The immediate result of treatment was satisfactory.

MICHAUX reported a satisfactory operation of this character upon a child aged nine years who had had a spinal deformity for three years.

BROCA reported three cases in which he had tried this operation; in one case all his strength was insufficient completely to reduce the deformity, which had existed a long time. In the other two cases, one of two-years' and one of about three-months' duration, the deformity was corrected without trouble. No unpleasant symptoms followed in any of these cases.

At the session of May 26th, MENARD made a plea for the conservative treatment of hip-joint disease in children because of the spontaneous cure which so often follows osseous tuberculosis in children. The fact that conservative treatment requires so much time is less of an argument with children than with adults. The majority of cases of coxalgia should be treated at the onset by immobilization, and not by continuous extension. The affected limb should be put in a position of medium abduction in order to avoid inward rotation, which is the principal danger of a vicious fixation in coxalgia.

KIRMISSON was opposed to all forcible correction of deformity in tuberculous troubles whether of the spine or hip-joint, or situated elsewhere.

At the Medical Society of the Hospitals, May 14, 1897, MARIE presented a man, aged thirty-nine, who seemed to be suffering from *hereditary hydrocephalus*. With him the lesion was congenital. His intellectual gifts were small except in the mechanical arts. Two children showed the same cranial condition as their father. This would seem to indicate that hydrocephalus is of hereditary origin.

CHASLIN was doubtful if the condition of the head, either in father or children, was really hydrocephalic.

At the session of May 21th, GAUCHER mentioned the good results which he has had in *the treatment of acute eczema by picric acid*. It is applicable only to the vesicular and weeping variety. As in cases of burns, he employs a one-per-cent. watery solution, saturating the compresses with it, and leaving them in place two days. At the end of this time inflammatory reaction is already subsiding, through the same application is repeated every two days as long as is necessary. The picric acid has a calming effect and rapidly relieves the itching. Gaucher believes that this treatment will be found applicable to other acute superficial inflammations of the skin, for example, in cases of pemphigus.

COMBY has six times observed a movable kidney in children. All of the cases were in females, four of the children being from ten to sixteen years of age. They had suffered for years from dyspepsia and pain in the right side. The other cases were found at autopsy in syphilitic infants, aged one and three months respectively. In both of the latter instances the trouble was bilateral and con-

genital. Comby suggests the hypothesis that all cases of floating kidney are congenital in their origin, or at least that an unusually long pedicle predisposes the kidney to be displaced by influences later in life, such as tight-lacing, and frequent pregnancy.

JACQUET mentioned a case of *muscular rheumatism* occurring in a man aged nineteen, *affecting the muscles of the loin, abdomen, and pharynx, it being secondary to an acute attack of gonorrhea*. The pain in the throat and upon swallowing preceded by at least forty-eight hours any evidence of inflammation in the mucous membrane, so that the inflammation in the latter undoubtedly seemed to be secondary to the affection in the neighboring muscles.

At the session of the Society of Dermatology and Syphilography, May 20th, FOURNIER presented a patient, aged forty-eight, who two months previously had had upon his hands and arms ulcers and granulations having *all the appearances of tuberculosis*. He denied syphilitic infection, and there was no reason to doubt his word. A diagnosis of tuberculosis was further justified by the fact that the patient was a chronic tuberculous subject. However, an injection of calomel was given him, and a stomatitis quickly produced, and there was a decided improvement in the ulceration. Second and third injections were made, and in a short time there was complete recovery.

AUGAGNEUR had seen tuberculous ulcerations in the person of a boy, aged eighteen, cured once by operation, but recurring after twelve years they disappeared after some weeks under treatment with iodid of potassium. A cure also followed the use of this drug in a patient who had an ulcer upon the left leg thought to be tuberculous.

JACQUET and SABOURAUD recalled similar instances in which undoubted tuberculous lesions disappeared under mercurial treatment.

The moral which FOURNIER drew from these facts was that the reaction which follows antisyphilitic treatment does not infallibly determine the diagnosis.

Vienna.

A CASE OF DIABETES MELLITUS THOUGHT TO BE NEPHRITIC IN CHARACTER—A SIGN OF TRICUSPID INSUFFICIENCY—HEMORRHAGE FROM THE FEMALE BLADDER, ITS CAUSES AND TREATMENT—THE VALUE OF CARBONIC-ACID BATHS—THE APPLICATION OF THIERSCH GRAFTS TO THE SURFACE OF A CAVITY.

At the session of the Medical Club, held May 5th, KOLISCH read a paper upon *diabetes mellitus*, referring to the fact that there are cases which are with difficulty classified either as "light" or "severe." As an illustration, he mentioned that a woman, aged twenty-five, who was troubled with thirst and frequency of micturition, came to him for treatment. The urine contained a great quantity of sugar. Thirst and polyuria diminished under a rather strict diet, and emaciation ceased. The specific gravity of the urine was about 1040 and the daily quantity about 1200 cubic centimeters (forty ounces). It was found impossible, even under a strict diet, to reduce the quantity of sugar below five per cent. Even when hydrocarbons were removed from the diet the sugar still made its appearance, but still without emaciation. Under the

circumstances, one had no right to speak of this case as one of "severe" diabetes. By testing the urine hourly after hydrocarbons had been ingested, it was found that it contained sugar only for a few hours after a meal, and, similarly, when albumen alone was given, the amount of sugar was greatest four or five hours after a meal.

KOLISCH described this case as one of tachyglycosuria and thought that the lesion might be in the kidney. As a matter of fact, the kidney secretes sugar whenever the blood contains even a fraction over the normal amount. In this case investigation of the blood showed that it contained no increase of sugar, which is characteristic in diabetes of kidney origin. This would also explain the absence of polyuria. The writer did not attempt to say whether this was a disease by itself or simply an early stage of ordinary diabetes.

TELEKY thought that a patient whose urine contained sugar, but who presented no other symptoms, should not be described as a diabetic. HERZ did not believe that in the case reported the lesion was confined to the kidneys, as the liver also must have been affected. SINGER thought the proof that the blood did not contain an excess of sugar was insufficient, as, if present, it might have been variable from time to time.

KOLISCH said, in reply, that although not many examinations of the blood had been made, for the reason that the patient could not bear it, yet the fact that examination was made and yielded a negative result at a time when the urine contained sugar, was good proof that there was no hyperglycemia. He thought one is justified in calling such a case diabetes, inasmuch as the presence in the urine of sugar is the one invariable symptom of the disease, and we know too little about diabetes to make a diagnosis when this symptom fails.

At the session of May 12th, BRAUN discussed *the signs of tricuspid insufficiency*. This may be either relative, produced by excessive dilatation of the right ventricle, or functional, as a result of imperfect action of the papillary muscle. He mentioned a case of tricuspid insufficiency in which, a short time before death, systolic pulsation appeared in the veins of the neck, while in the cardiac area pulsation could be seen in three places—the usual pulsation over the apex of the heart in the fifth left interspace, a double pulsation in the third left interspace (the first being lower than the second), and a third pulsation in the second interspace to the left of the sternum and close to it. This pulsation began as a pre-systolic one and grew stronger during the systole, which it outlasted. Braun had proved by autopsy that this pulsation in the second left interspace could emanate only from the right auricle or its appendage, and he therefore regards its occurrence as a reliable symptom of tricuspid insufficiency only to be seen in connection with a considerable amount of dilatation.

KOLISCHER spoke of *hemorrhage from the female bladder*. The use of the endoscope and cystoscope has shown that many of the theories in regard to this subject are false. Hemorrhage occurring before the stream of urine has its origin in the urethra. The most frequent causes of it are polyps, which are really angiomas, and

gonorrhea; in the latter trouble therapeutic measures, such as the introduction of too hard medicated pencils may bring about hemorrhage, with severe results. It was previously supposed that the passage of cylindrical blood-clots was absolute evidence of hemorrhage either from the ureter or kidney. The cystoscope has shown that such is not the case.

Hemorrhage from the bladder may be due to new growths, inflammation, injury, as by instruments, or to alteration in the blood-vessels. New growths are a far less frequent cause of hemorrhage than is usually supposed. Here, too, the commonest cause is gonorrhea. Malignant tumors in the vicinity may produce degeneration of the blood-vessels of the bladder, with resulting hemorrhage. This takes place, for instance, in carcinoma of the uterus. Chronic inflammatory processes produce excrescences in the vicinity of the urethral orifice, and if these are torn off during urination or as result of examination, hemorrhage follows. The cystoscope has shown also that the bladder, even in women who have not borne children, may contain varices, and these are liable to burst and produce troublesome hemorrhage.

The treatment in all of these cases is the introduction of cold water, preceded if necessary by a curettage. The introduction of styptic substances, such as chlorid of iron, is dangerous. Tamponing the bladder is not to be advised. The most radical measure is suprapubic cystotomy. In using the cystoscope to establish the diagnosis of tumor of the kidney, at the time of examination perhaps no blood may be seen to issue from the mouth of the ureter, although the urine invariably contains blood. Very often in such a case pressure in the lumbar region will cause blood to flow from the ureter and thus establish a diagnosis.

At the session of May 19th, RUDINGER discussed the value of baths containing carbonic dioxid, which were first employed at Nauheim, where there are natural springs containing this gas. The attempt to produce such baths by a mixture of carbonates and hydrochloric acid has proved unsatisfactory. If the compressed gas is simply allowed to flow through the water of the bath, it almost all escapes, but an apparatus has been devised by Lippert which mixes the water and gas before the water is allowed to flow into the tub, and by this apparatus the water can be charged with gas up to fifty per cent. of its value. Rudinger has devised an improvement by which the water is made to take up one and one-fifth volumes of the gas in a short space of time.

REITHOFER has employed these baths with excellent results in neurasthenia, myalgia, neuralgia, and for the lancinating pains of tabes dorsalis.

HERZ, who studied the treatment at Nauheim, was in many respects disappointed. One woman, whose aortic insufficiency was said to have been much benefited, was found by him never to have had an aortic lesion. He also saw several cases in which the baths and accompanying gymnastic exercises were followed by tachycardia and an increase in the area of cardiac dulness. At Nauheim the patient's head remains in an atmosphere charged with carbonic bioxid, while those who prescribe the artificial

baths are careful to see that the patient breathes pure air during the bath.

At the session of the Imperial-Royal Society of Physicians, held May 14th, GERSUNY mentioned two instances in which he attempted to apply *Thiersch grafts to the surface of a cavity*. In the first case, diphtheria had produced an almost complete cicatricial stenosis of the larynx in a child one year and nine months of age, and breathing was only possible through a cannula in the trachea. Gersuny divided the larynx, excised the cicatricial mass, and covered the circular denuded area, which was left with a graft taken from the thigh, and in order to keep it in place the cavity was tamponed and the skin sewed together over it. In eight days the tampon was removed and the flap was nicely united. The cannula was kept in position for some time, and the larynx was dilated with bougies and tubes, as there was some tendency toward contraction. The cannula was at last dispensed with and the child breathed normally.

In another case, in which over an inch of the urethra was obliterated, the urine being passed through a fistula, the scar was excised and a graft placed in position much as in the other case. Instead of a tampon, however, a catheter was introduced and left in position for some days. The result was perfect, and contraction is not to be feared, as the new canal is somewhat larger than the old.

At the session of May 24th, WALDSTEIN showed a case of *cleft pelvis with epispadias and ectopia vesicae* in a woman aged thirty-three, the peculiar feature being that the bladder was completely closed. This combination has been reported only three times, namely, in boys aged respectively fifteen months, eighteen months, and six years. In the case presented, the labia majora and minora were separated anteriorly about a finger's breadth, the clitoris was divided, and immediately under it there was an opening about one-half an inch in length, through which a sound passed in one direction into the bladder and in the other through a normally placed meatus urinarius into the vestibule. The patient was seven-months' pregnant. Waldstein believed that a normal birth for both mother and child is possible.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held May 19, 1897.

The President, DR. CHARLES L. DANA, in the Chair.

DR. JOHN F. ERDMANN presented a patient from whom he had removed the left half of the inferior maxilla for carcinoma. The man was a longshoreman, fifty-five years of age, whose family history was good. He was first seen February 15, 1897, at which time there was a hard lump on the inferior maxilla and also ankylosis of the jaw. The growth was hard, ulcerated, discharging freely, and involved the tonsil, pillar of the left fauces, sulcus of the mouth, and the left side of the tongue. There also was some enlargement of the cervical glands

on the same side. On February 22nd the speaker removed the glands, and it was found necessary to excise four and a half inches of the internal jugular vein and also half an inch of the pneumogastric nerve. The external carotid, external lingual, superior thyroid, and facial arteries were ligated. The wound healed by first intention. There was a slight brassiness of the voice, which, however, disappeared at the end of ten days. Three weeks after the first operation, the left half of the inferior maxilla, together with the tonsil, pillar of the fauces, half an inch (in depth) of the wall of the pharynx, mucous membrane on the posterior half of the left cheek, and the side of the tongue were removed through Kocher's incision. The patient made a good recovery, and there is no evidence of paralysis of the vocal cords as a result of excising the pneumogastric nerve, nor has it had any effect upon the pulse-rate.

DISCUSSION.

DR. E. S. PECK thought it remarkable that a man as old as the patient should have survived such a number of ligations.

DR. JOSEPH COLLINS said that exsection of the pneumogastric must naturally strike those of us who studied physiology ten years or more ago as being very remarkable. Then it was taught, and is now by many, that such injury must necessarily be attended with decided perversion in rhythm and rate of the pulse and changes in blood pressure. Jendrassik has recently stated that the pneumogastric is not a cerebrospinal nerve, but that its function is purely vegetative. Having this in mind, he would look for some trophic change in Dr. Erdmann's patient, and asked the latter if careful examination had been made for any change in the pupils and circulation on that side. Although not willing to go as far as this, the speaker thought it more than likely that all the fibers furnished by the so-called vagus nucleus, the vago-glossopharyngeal nucleus, are vegetative.

The PRESIDENT said that symptoms often occur in surgical practice which might be confounded with neuritis of the pneumogastric. He had seen several cases in which the latter followed grippe and in which there was paralysis of one of the vocal cords, but no change in the heart's action. The speaker did not agree with Jendrassik that the pneumogastric is a purely sensory nerve, for there are motor as well as sensory fibers in its trunk.

DR. ERDMANN, in closing, said that no study had been made of the trophic changes, because the patient disappeared and was lost sight of for a time. He added that Roswell Park has mentioned a number of cases in which the pneumogastric has been divided, on both sides in some instances, without serious results.

DR. S. BARUCH then read a paper, entitled

THE HEALTH RESORTS OF EUROPE. (See page 33.)

DISCUSSION.

DR. ROBERT MILBANK regretted that he had not heard all of the paper, which was most interesting, and thought we should have in this country sanatoria similar

to those in Europe, as described by the author. Results obtained here would then be as good as those secured abroad.

DR. WILLIAM STEVENS said that rest, diet, and hydrotherapy are beneficial in many cases and wonderfully effective in lung diseases, and hoped that the author could tell us of similar places in this country where patients might be sent.

DR. H. L. TAYLOR thought the observations made by the author while abroad should have a great deal of influence in the conduct of sanatoria in this country. He referred to several in this State, and said that the average large sanatorium is conducted as a commercial enterprise, unscientifically, and prevaded by an atmosphere of sentimentality which is absolutely detrimental to many of the patients.

DR. J. H. FRUITNIGHT was especially impressed by the fact that open air is largely relied upon in sanatoria devoted to phthisical patients. He was heartily in favor of such treatment.

DR. ROBERT NEWMAN said that such a beautiful narrative as the author's paper could hardly be discussed. He regretted that there are in this country no proper sanatoria for the treatment of consumptives, and said that in some it is remarkable to see how the simplest sanitary rules are neglected.

DR. R. A. MURRAY thought that failure with the use of natural means of cure, *i.e.*, air, water, and rest, is due to lack of facilities and personal supervision on the part of the physician. That a great deal of good is to be obtained by these agents is evident from the results secured in Germany, where the treatment is scientifically carried out under the direction of competent physicians.

DR. J. BLAKE WHITE expressed the opinion that too little attention is paid to the selection of a proper resort. A patient suffering from lung disease is sent to a certain place, simply because there is a sanatorium there and without considering whether or not it is suitable for the particular case. Many phthisical patients cannot stand the cold winters of the Adirondacks, yet it is common practice to send them there.

DR. PECK considered the paper very instructive, inasmuch as it called attention to many health resorts in Europe the existence of which is not generally known. He is heartily in favor of institutions where treatment can be carried out under medical supervision and amid pleasant surroundings, and is glad to know that in Germany especial attention is paid to old chronic cases of rheumatism, syphilis, etc. American physicians, the younger men particularly, are apt to be impatient and will not wait for the beneficial results which follow this mode of treatment.

DR. S. H. DESSAU thought there could be but one opinion in regard to the value of the paper, and said that thanks are due the author for bringing home to us such a detailed report of his observations abroad.

DR. BARUCH, in closing, said his idea in presenting the paper was to emphasize the importance of methodical and systematic treatment of chronic disease—a point which medical men are apt to neglect—and hoped it

would prove an incentive to some members of the profession to establish sanatoria in this country where such treatment could be carried out.

DR. JOHN F. ERDMANN presented a specimen of jejunum removed from a man who was shot a few days before. The bullet entered at a point within half an inch of the raphe between the two buttocks and about two inches from the coccyx, passed through the great sacro-sciatic notch, traveled along the posterior wall of the pelvis postperitoneally, punctured the peritoneum at the brim of the pelvis just outside of the ureter and iliac vessels, and was found lying beneath the superficial fascia at a point half an inch above the umbilicus and an inch and a half to the right of it. Celiotomy was done and twenty-five inches of intestine in which there were fifteen perforations were removed, and the gut united by a Murphy button. A Meckels diverticulum about an inch in length was found in the portion of intestine removed. The man was in a stooping position, crouching behind a wagon, when he was shot, and this accounts for the wound of entry. When first seen he had a temperature of 106.8° F. and was profoundly septic. During the operation five pints of salin solution were injected in the right median basilic vein. A tampon was left in the abdomen near the Murphy button, and another at the brim of the pelvis. Very free drainage took place, and the dressings had a strong odor of urine. The man died of acute septicemia on the third day. At the autopsy no evidence of injury to the ureter was found.

DR. ERDMANN also showed an inferior maxilla removed from a woman forty-three years of age, whose family history was negative. Some time ago the woman had a molar tooth on the right side extracted and the socket never healed. She then had a wisdom tooth extracted, after which a tumor began to develop. At first there was no pain accompanying the growth, but later she suffered pain at night and occasionally during the day. Examination showed a hard humor about the size of an egg, which extended under the maxilla and proved to be an osteosarcoma. The wound healed by primary intention and hardly any scar remained. There was but little deformity as a result of the operation.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 1, 1897.

The President, B. SACHS, M.D., in the Chair.

A CASE OF INTRASPINAL TUMOR OF THE CERVICAL REGION, MISTAKEN FOR HYPERTROPHIC CERVICAL PACHYMEINGITIS.

DR. JOSEPH COLLINS read a paper with this title. (See page 48.)

DR. F. PETERSON asked if there were any other sympathetic symptoms besides the diarrhea.

DR. COLLINS said that he had not seen the patient until a few hours before death, and at that time such sympathetic symptoms as were present were looked upon as ante-mortem ones.

DR. GEORGE W. JACOBY did not think there was a sufficient basis for a diagnosis of hypertrophic cervical

pachymeningitis unless there were present the symptoms considered characteristic of that disease. The case just reported presented a pure symptomatology of a growth.

DR. L. STIEGLITZ said that in the differential diagnosis of a tumor of the cord and pachymeningitis cervicalis, the asymmetrical character of the symptoms should be taken into account—the pain and paralysis existing in one arm only for some time. He could not agree with Dr. Collins that symptoms of tumor of the spinal cord are almost entirely root symptoms, for the exaggerated knee-jerk is an early symptom.

THE PRESIDENT said with regard to the symptomatology that the root symptoms are generally the earliest ones, but other symptoms, such as the exaggeration of the reflexes, will appear relatively early if the tumor is sufficiently large to produce pressure upon the lateral columns. The curious thing about tumors of the spinal cord is that the unilateral character of the symptoms disappears at a very early period, and does not necessarily denote any actual invasion of the spinal cord substance; they are due simply to the effect of pressure. He had been interested in the sympathetic symptoms. It had been quite generally supposed at one time that the secretion of the kidneys is very much influenced by disease in the cervical portion of the cord, but experiments made years ago by several investigators, including himself, had cast some doubt on the correctness of this view. Eckhardt has found that interference with the ureters in the earlier experiments was apparently responsible for the inhibition of the renal secretion, and that the cord had nothing to do with it. The speaker said that pachymeningitis hypertrophica cervicalis has always been more or less of an enigma to him; he has seen very few cases corresponding to the description given by Charcot, and was in some doubt as to whether it represents a disease *sui generis*.

DR. MARY PUTNAM JACOBI suggested that as a chronic pyelitis had been found in Dr. Collins' case, it was possible that a parenchymatous nephritis had been grafted upon it, and that the diarrhea was simply a uremic symptom.

DR. COLLINS said that the point made by Dr. Stieglitz was extremely well taken. Spinal cord symptoms do not appear in pia tumors until toward the end, or when the tumor is of considerable size. Small tumors rarely make pressure on the cord itself, because the pia is not bound down by diverticula, and hence, has room to expand; but, as Dr. Stieglitz had very well said, in large and rapidly growing tumors, and, of course, in tumors of the medulla itself, the reflex symptoms are very early and significant. He had been led to believe from some recent investigations on the sympathetic nervous system, that the diarrhea was a sympathetic symptom. He believed that the sympathetic symptoms present in this case, of which diarrhea was one, and the urinary complication probably another, were due to a secondary degeneration or myelitic process set up after the disease had become well developed, and to implication of the medullary substance of the cord from the pressure of the tumor.

KATATONIA.

DR. FREDERICK PETERSON read a paper founded on

four cases of katatonia that he had personally observed at the Hudson River State Hospital at Poughkeepsie. Katatonia, he said, is a term applied to a certain group of psychical and motor symptoms which have often been considered as constituting a new and distinct form of insanity. He quoted the opinions of a number of authorities showing that katatonia has been looked upon as a clinical entity, as a variety of melancholia, as a form of circular insanity, as a species of hysteric insanity and, by one author, as atonic mania. The symptoms are essentially variable, and exhibit a tendency to change from phase to phase, often returning to a previous one. The earliest symptoms are: Abnormal sensations in the head, vertigo, insomnia, irritability, and a certain amount of gradually increasing melancholia. The second stage may be ushered in by convulsions, or the patient may become maniacal. Muscular tension and spasmodic movements are present. Rhythmical movements are often seen, but are always under the control of the will. Sometimes there is a condition of religious excitement; sometimes a tendency toward talking and acting theatrically, with perhaps a tendency to rhyming will be observed. Catalepsy is often extreme, and the muscles are generally in a state of tension. It is an extremely rare condition, he thought, presenting a symptom complex observed in many cases of insanity. The katatonic state can be distinguished from the insanity of pubescence by the fact that the delusions of the former are intellectual, depressed, and varied indefinitely, while in the latter, there are vague and stupid delusions. The chief diagnostic difficulty lies in differentiation from such cases of melancholia as manifest atonic or cataleptic states, but the rhythmic movements and tendency to repeat words and strike attitudes are important differential points. It is to be differentiated from hystero-epilepsy by the history rather than by isolated symptoms. From chorea it is distinguished by the fact that in chorea the movements are irregular and involuntary, and are not apt to exhibit such a variety of phases.

DR. PETERSON reported four cases—the only ones met with in a considerable experience extending over fifteen years. The following case was typical of them all: B. R., female, thirty-one years of age, married, possessed of a common education. She was admitted to the Hudson River State Hospital during February, 1884. There was no hereditary history. The first evidence of mental disturbance manifested itself in August, 1883, two months after the birth of one of her children. She developed complete anorexia, lost interest in her surroundings, and, three weeks before admission, became suicidal. Menstruation was regular. The case was at first regarded as one of puerperal melancholia. On February 11 she tried to beat herself against the bedstead, and claimed that she was being poisoned. She passed quickly into a condition of noisy excitement, and refused all food. She was markedly suicidal. She showed symptoms of exhaustion, and was fed by a tube for a considerable period. On March 15th she became cataleptic, and was absolutely silent, noticing no one, not even her husband. She began to wet and soil the bed. After a month or more she began to destroy her clothing and become filthy in

her habits. In November, 1884, she began to cry out repeatedly, "Bring me to my children in New York," and this was repeated over and over again in a rhythmic manner, and more markedly on alternate days. After awhile she began to rhyme with a series of unintelligible words. Meanwhile she was improving in her general condition. In the autumn of 1886, improvement was very evident, and after a short time she was allowed to go home. A recent report shows that she has recovered completely and permanently. Each one of the other three cases began as a case of melancholia, in which cataleptic conditions developed, and then this phase of verbigeration with rhythmical movements was added. One very prominent feature of all four cases was the melancholia. The verbigeration and rhythmic gesticulations were, perhaps, the most characteristic features.

His conclusions were: (1) That katatonia is not a distinct form of insanity; (2) that it has no true psychical character in its manifestations, and, hence, cannot be classed as a form of circular insanity; (3) it is simply a type of melancholia, and it is not desirable, therefore, to retain the name "katatonia." Katatonic melancholia would be a convenient descriptive term. He was of the opinion that the prognosis in melancholia with katatonic symptoms is more grave than in any other form. The treatment is the same as for melancholia.

DR. WILLIAM HIRSCH said that he had studied these cases while an assistant of Kahlbaum, who had originally described the disease. Katatonia is only one of a number of peculiar forms of insanity that Kahlbaum has created. The speaker said that he had very carefully studied the records of the cases which Kahlbaum had himself diagnosed as katatonia, but he could never convince himself that katatonia was a distinct clinical entity. In none of these cases could there be found a single symptom which was not sometimes present in other forms of insanity. Kahlbaum claimed that katatonia gives a very favorable prognosis, yet a celebrated pupil of his had recently published the statement that the prognosis is very bad. In 1874, Kahlbaum had asserted that katatonia is an organic disease, and had published certain pathologic descriptions in support of this position. This seemed to be directly opposed to his estimate of the prognosis, and he believed that Kahlbaum has since abandoned these views.

DR. WILLIAM LESZYNSKY asked Dr. Peterson if those cases which show cataleptic symptoms also exhibited symptoms of trance at the same time.

DR. PETERSON replied that they had not done so any more than the ordinary cataleptic.

DR. LESZYNSKY recalled a case in his practice in which the patient had become cataleptic, and had remained in a trance state for three months. A certain surgeon had removed both ovaries from this patient, with the idea of curing her. A curious feature was that she became conscious some time before death, and told him in the presence of others that she had been perfectly conscious of what had taken place during the previous few months, and proved her statement by recalling certain incidents.

DR. HALLOCK said that he had seen two cases of katatonia. One of these had passed into dementia; the other had been considered at one time to be a case of melancholia, but the later symptoms had been of a hysterical order. The katatonic symptoms had finally passed off, and the patient had made a good recovery.

DR. RAFEL remarked that there must necessarily be great confusion if, as Kahlbaum had stated, any one of the phases might fail.

DR. PETERSON, in closing the discussion, said that most of those who have followed Kahlbaum have looked upon the prognosis as very grave, some authorities having placed the recoveries at three per cent. Of the four cases reported in the paper, one patient recovered. In the fatal cases, the patients passed into a condition of dementia, and generally died of tuberculosis, which is also consistent with the idea that katatonia is a variety of melancholia, as this is a common termination in melancholia.

REVIEWS.

ANATOMY. DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F. R. S., Lecturer on Anatomy at St. George's Hospital, London. New and thoroughly revised American edition, much enlarged in text, and in engravings both colored and black. In one imperial octavo volume of 1239 pages, with 772 large and elaborate engravings on wood. Lea Brothers & Co., publishers, Philadelphia and New York, 1896.

A DICTIONARY is the great balance-wheel of the language of a people. It establishes the lines along which the development of a language may advance, and, at the same time, it holds in restraint a too rapid progress in directions which tend to deteriorate rather than to improve. In the authority of its utterances and in the respect in which it has been held by generations of medical students and practitioners, Gray's "Anatomy" bears about the same relation to anatomic literature which the general lexicon bears to a nation's language. The emotions that its presence recalls are most conflicting. There are times in every medical student's life when he feels as he takes it from the shelf that no wildcat that he may be called upon to master could possess more venomous teeth and claws than are contained within the covers of this venerable book. At other times the lucidity of its descriptions and the accuracy of its illustrations afford the keenest delight. From these conflicting emotions a love and veneration are begotten which endure through a professional career. It is, therefore, with no slight degree of gratification that this new edition is welcomed from the press of Lea Brothers & Company. Not only has there been a general revision of the work as a whole, but in certain departments in which investigation has been especially active during recent years radical changes have been introduced. The sections which have been rewritten are those on the brain, the teeth, and the abdominal viscera. The chapters on histology and development, a feature peculiar to Gray, and one of inestimable value in affording a key to what

would otherwise prove anatomic mysteries, have also been revised in accordance with the latest discoveries in this field of work. "Gray" has always been distinguished by a series of splendid illustrations. These have been enriched in this new edition by no less than one hundred and thirty-five additional engravings. In these, distinctive colors have been used to give greater prominence to the veins, arteries, and nerves, as well as to the attachments of muscles. In mechanical execution no effort has been spared to render this work worthy of the continued reputation won by "Gray" in the past as the foremost of medical text-books. This new American edition is destined to maintain in every respect the exalted position which for many years the work has enjoyed.

A TEXT-BOOK OF BACTERIOLOGY, INCLUDING THE ETIOLOGY AND PREVENTION OF INFECTIVE DISEASES, and a Short Account of Yeasts and Moulds, Hæmatozoa, and Psorospers. By EDGAR M. CROOKSHANK, M.B., Professor of Comparative Pathology and Bacteriology, and Fellow of King's College, London. Fourth Edition. Philadelphia: W. B. Saunders, 1896.

ALTHOUGH this well-known work is now in its fourth edition and has been increased by the addition of twenty-six new chapters, still it does not embrace all the recent advances made in the department of bacteriology. After a rather careful reading of the book we have been impressed by the fact that the author is far more profoundly informed in animal, than human, bacteriology. For instance, the chapter on malarial fever covers four pages, while fifteen pages are devoted to hæmatozoa in horses, fishes, rats, and frogs, and seventeen pages to an outbreak of cow-pox in Wiltshire, with the author's investigations to disprove the Local Government Board's idea that scarlet fever has its origin in cows. When one considers that more than thirty pages are given to actinomycosis and but one page to gonorrhœa, it will be noted that the work is not as evenly balanced as it might be.

The methods of staining bacteria should have been more minutely described, also the preparation of sections. If a student has no knowledge of histological methods in general, this work hardly explains the details clearly enough for his needs, and therefore as a text-book on bacteriology it cannot be compared with some of the recent books with which we are familiar.

A chapter on photography has been added and the methods are clearly but briefly outlined. A chapter on the classification of species for diagnosis, modeled after Eisenberg, and a short account of each organism arranged for easy reference, increase the value of the book. Space does not admit of our reviewing this work as fully as we should like, but we can heartily commend it as a work of reference to the advanced student, particularly to those interested in diseases of the lower animals. The chapter on actinomycosis, for example, is the best that we have seen in any text-book. The text is remarkably free from typographical errors, the type and paper are excellent and the illustrations are profuse and for the most part superb.

SERUM-THERAPY IN ACUTE SURGICAL INFECTIOUS DISEASES.*

By HOWARD LILIENTHAL, M.D.,
OF NEW YORK;
ASSISTANT SURGEON TO MT. SINAI HOSPITAL.

TWENTY-SIX years ago, Sir James Paget devoted several pages of the *Lancet*¹ to a paper on dissection poisons. The thoughts there so vividly and elegantly expressed were suggested by the distinguished author's recent personal experiences with septicemia, which he incurred while examining *post-mortem* the body of a man who died of acute sepsis following lithotomy. The observations and speculations of Paget are most interesting when we think that they were made before the germ theory of disease had been accepted and before anything was really understood of the true pathology of wound-infection. Paget observes that "not all men can be made ill by a virus from a dead body, nor can the same man be made ill at all times; but there must be what is called a fitting soil for the virus to work in. We know no more what this soil is than we know what the virus is." And again, further on, he observes that "a chief interest in reference to these various susceptibilities to the influence of the virus from dead bodies is, that *one may become insusceptible* [*italics mine*]. They who are day after day engaged in *post-mortem* examinations usually acquire a complete immunity from the worse influences of the virus. . . . They do not suffer with any infection of the lymph or blood."

This was written in 1871, and twenty years and more elapsed before the first attempts at artificial immunization were made. Yet now that the ice has been broken, the activity in this field of research has become enormous. The amount of literature during the last eighteen months on the cure and prevention of infection by the use of substances prepared by Nature herself in mammalian bodies is truly astonishing. I shall not here take time to describe the progress in this new and fascinating study; it was excellently done by Roger and Haushalter but a few months ago.²

Experimental work in the serotherapy of acute surgical infections has its object in combating the various pathogenic organisms—for example, the colon

bacillus by Drs. Albaran and Mosny,³ bacillus pyocyaneus, the bacillus of glanders, anthrax, and the staphylococcus by Kose and others,⁴ the bacillus of tetanus by Behring, Kitasato, Tizzoni, and others,⁵ and the streptococcus by Marmorek and many others. The actual value of the serum treatment of disease caused by these micro-organisms in the human subject is not yet determined, though in the laboratory animals are immunized, cured, or killed with a pretty fair amount of precision.

Tetanus.—Hewlett⁶ quotes Sir Astley Cooper to the effect that a patient with tetanus may recover spontaneously, but he believes that the antitoxin should be used in all cases, and very early. A case reported by J. W. Cokenower of Des Moines⁷ but a few weeks ago is of great interest. A man infected about six days before had seventy-five convulsions per hour. After antitoxin had been given, the spasms were reduced to ten in an hour, and there was marked general improvement. Unfortunately, the supply of antitoxin gave out, there was a return of the evil symptoms, and the man died.

Dr. Trapp⁸ of Helferich's Clinic in Greifswald, reports a most malignant case of tetanus with opisthotonos and severe and lasting trismus cured after injections of Tizzoni's antitoxin. Trapp's impression of the antitoxin treatment is very favorable because of the rapid improvement noted. He recognizes the fact that the man might have recovered without antitoxin, but cannot help believing in its efficacy.

Tetanus, fortunately, is not a common disease, and its percentage of mortality varies so widely according to different observers that an accurate estimation of the value of serotherapy in its treatment may hardly be expected in the near future. It is probable, however, that the antitoxin, if it is to be of real benefit, should be employed as a prophylactic, especially in cases in which suspicious wounds occur during the progress of an epidemic of tetanus. If we wait until the characteristic symptoms of the disease are present, we wait for the occurrence of general infection and lose valuable time.

Pyogenic Infection.—The investigations in serotherapy as applied to the colon bacillus, anthrax, staphylococci, etc., are as yet not sufficiently tested to warrant more than their mention here. I shall therefore discuss only the work which has been done to counteract the evil effects of the streptococcus.

* Read before the Surgical Section of the American Medical Association, Philadelphia, June 3, 1897.

Marmorek,⁹ in 1895, produced a serum by successive inoculations of the horse with increasingly virulent cultures of the germs. This or similar serum has since been produced by numerous others, and a considerable number of cases have been recorded by various clinical experimenters in which this remedy has been used. It has been tried in the various forms of surgical infection, whether the source of the trouble was found to be due to the streptococcus or not, as, for example, in erysipelas,¹⁰ in puerperal fever,¹¹ in septic peritonitis, and in other general acute septic infections.

Chantemesse,¹⁰ in erysipelas, reports a marked diminution of the death-rate in those patients treated by the stronger serums, and has never noted ill effects. Delirium and the pulse were usually improved after the injections. Bolognesi¹² criticized Chantemesse, saying that it would be necessary to note the *type* of erysipelas (malignant or not) treated by the serum. It seems to me, however, that inasmuch as one would hardly accuse an investigator of picking out the milder cases for serotherapy, the difference in the death-rate with and without serum treatment in several hundred cases is worth noting and this even in view of the fact that Koch and Petruschky¹³ have not observed *immunity* from erysipelas after previous attacks or after inoculations with antistreptococcic serum. Merieux and Niemann¹⁴ say, however, that Petruschky used the wrong kind of serum in his experiments, and they maintain that good results in immunizing animals may be obtained by using another preparation. Aronson¹⁵ believes that the carbolic acid used ($\frac{1}{2}$ per cent.) to preserve Marmorek's serum gradually destroys the "antibodies" or substances which form the active principles of the serum, and that if a pure serum unmixed with carbolic acid be used it will immunize.

It would not be right for me to take up more of your time by proceeding further in this line. It is enough to say that investigators differ widely in their reports, and that experiments with serum-therapy in treating the human subject, whether for erysipelas or general infections of other kinds, vary so greatly in their results that we must be slow to form an unprejudiced opinion. In the meantime, all new cases should be recorded so that at some time in the future the evidence on which to base mature judgment may not be wanting. It must also be remembered that, after all, the streptococcus itself is not well understood. I need but say that Nocard¹⁶ has shown that of two equally malignant cultures, the one injected into a horse may be counteracted by Marmorek's serum, while the other is absolutely uninfluenced by it, to give you an idea of the great difficulty of forming a scientific opinion.

I shall, then, simply add my mite to the knowledge we have on this subject by recording here some clinical experiences with serum treatment in acute surgical infections, and I believe that, after all, the history of a personal success or failure is of practical value in influencing the line of treatment of others who may be confronted by similarly grave problems. Most of the cases here reported have not been published, but one or two which have been referred to or presented at the meetings of medical societies are sufficiently striking to be again brought forward.

CASE I.—This history, which was very lately published by Melloni of Rome,¹⁷ illustrates a class of cases in which the use of diphtheria antitoxin has been followed by cure, though no Klebs-Löffler bacilli were present. The disease was diagnosed as "hospital gangrene," and staphylococci and streptococci were found in the wound. It was a case of perineal abscess with urinary infiltration. Incision and drainage were followed by rapid and severe sloughing with the formation of "diphtheritic" membrane. There was high fever. Ten cubic centimeters of Behring's serum were given and the temperature rapidly fell. Another dose was administered followed by the rapid appearance of a demarcation line, and subsequent uneventful recovery.

CASE II.—This case occurred in the practice of Dr. R. Abrahams of New York. The patient was seen twice in consultation by Dr. Mundé. On February 15, 1897, six days after confinement by a midwife, the woman, a primipara twenty-six years old, was desperately ill. The abdomen was distended, the pulse rapid, the temperature 106° F. Involuntary urination and defecation were present, and there was a trace of albumin in the urine. A stinking, sloughy, "diphtheritic" membrane covered the raw surface of a complete laceration of the perineum, and a membrane was also seen on the palate and tonsils. There was, unfortunately, no bacteriologic examination, but the gentlemen in charge agreed that, clinically, it was not a case of true diphtheria. A single injection of No. 6, New York Board of Health diphtheria antitoxin was given, and was followed by a rise of temperature to 107° F., then by a fall of 1° per hour until the normal was reached. The patient fell into a sleep and recovery was rapid and unimpeded.

I am aware that the omission of a bacteriologic examination was unfortunate, but the case forms an interesting parallel with the first. T. J. Bokenham,¹⁸ in a discussion in England two years ago, noted that diphtheria antitoxin seems to act against streptococcic infection.

CASE III. is one of my own. It illustrates the use of antistreptococcic serum as a prophylactic. This use of the serum in cases where infection is to be expected had already presented itself to my mind when I read a report by W. Watson Cheyne,¹⁹ who says that in three cases of extensive operation about the mouth and throat previously treated with serum

there was a remarkably clean appearance during the healing of the wounded surfaces, with entire absence of the usual superficial sloughing. The breath, too, was remarkably free from odor. My patient was a woman about sixty-five years old, who had an epithelioma of the corner of the mouth requiring a wide extirpation. She received twelve cubic centimeters of Gibier's serum the day before operation and a like dose just before she took the anesthetic. Immediate healing was perfect, but a buried suture some days later formed a small abscess and came away. There was no constitutional disturbance at any time after the operation, even when the stitch came away.

CASE IV.—L. S., service of Dr. Gerster at Mt. Sinai Hospital. A girl of eighteen had violent general sepsis after an excision of the knee. No bacteriologic examination was made, but the general symptoms were most grave. There was stupor, rapid and weak pulse, fever, albuminuria, and icterus. A systolic murmur also appeared. She had seven injections of serum, eight to eleven cubic centimeters, and died March 6th, nineteen days after operation. The first injection of serum was not given until four days after the excision. The albuminuria *disappeared* and for a time her mind became clearer.

CASE V.—George G., aged fourteen, service of Dr. Gerster, the first patient to be treated with antistreptococcic serum at Mt. Sinai Hospital. This was on March 13, 1895. The boy had acute osteomyelitis of the femur, the tibia, and the jaw. His condition appeared hopeless, and two doses of the serum were given. Recovery followed.

CASE VI.—Bertha U., aged thirty-six, was operated upon by Dr. Van Arsdale at Mt. Sinai Hospital. She was intensely septic from an extensive gangrene of the gall-bladder, and it was thought that she would die. Collapse was so great that saline infusion was three times performed. She recovered after five injections of the serum. An improvement in the pulse was noted after the injections.

CASE VII.—Tillie M., aged twenty-one. Polyarthritides after puerperal sepsis. She was a patient of Dr. Gerster. She was not violently septic, but her condition was very wretched and she suffered intensely. She received five injections. A smart reaction followed the last one, with temperature 103° F. and pulse 140. Urine was negative throughout. Recovery.

CASE VIII.—Jacob W., aged twenty-five, patient of Dr. May at Mt. Sinai Hospital. Otitis media with possible brain abscess; acute sepsis; pleurisy. Two injections. Died.

CASE IX.—C. D. T., writer's case. Multiple bone tuberculosis; numerous operations. Four injections of Gibier's serum, six cubic centimeters each. There was no appreciable result. The patient eventually recovered.

CASE X.—R. B., aged thirty-three, was operated upon by me, May 3, 1897, for acute appendicitis. The abscess was accidentally ruptured into the peritoneal cavity. The cavity was not washed

out. She at once was given a *quasi* prophylactic injection of seven cubic centimeters of Gibier's serum. Recovery was uneventful. A culture from the abscess contents proved to be one of the colon bacillus.

CASE XI.—Boy of ten, with severe general septic peritonitis from a perforative appendicitis, had one dose of serum, but died a few hours after operation.

CASE XII.—This case is the last on my list and is, I believe, the most important. It is to my mind even more remarkable than the one reported by Ballance and Abbot²⁰ in which a physician suffering from fulminant general sepsis with hemorrhages recovered, apparently in consequence of treatment with antistreptococcic serum.

F. F., a girl eighteen years of age, and previously healthy, was attacked with severe osteomyelitis of the right femur. She had great pain, high temperature (104° F.) and rapid pulse, with slight icterus. On December 15, 1896, at Mount Sinai Hospital, just six days after the very first signs of the disease, I saw her and operated at once, exposing the marrow at the lower end of the shaft. The periosteum peeled easily from the bone, the bone cortex did not bleed, and the marrow seemed to contain too great an amount of free fat, but no pus was present. The wound was packed. After the first reaction of the operation, the temperature receded to 100.7° F. on the following day and the pain completely disappeared so that no opiate was required. The patient's mind, however, seemed a little dull and there was abdominal distension. The urine contained an excess of urates, but was of sufficient quantity. On the third day, December 17th, the maximum temperature was but 99.6° F., with pulse at 84, but more marked icterus and a distinct mental wandering. On the fourth day there was a frightfully rapid change for the worse, the patient becoming stuporous, and more icteric, with bile in the urine, *dilated pupils*, and rapid pulse. The wound was dressed. It looked "dirty," and an abscess was incised, under cocaine, just above the quadriceps bursa. The pus, examined at once by Dr. Elsberg, assistant pathologist to the Hospital, was teeming with streptococci in very long chains. This dressing was done in the morning; during the afternoon the girl's condition became still worse, the urine contained a trace of albumin, the pupils became widely dilated and did not react to light, the stupor amounted to coma, and at intervals, especially when she was touched or in any way disturbed, she emitted a peculiar loud and piercing shriek. There was distension of the abdomen and vomiting. The urine had to be drawn by catheter, and afterward came involuntarily. The temperature was still but 100° F., but the pulse was small and irregular, 140 beats to the minute, in spite of the administration of digitalis; respiration 36. Later in the afternoon things became so much worse with such astonishing rapidity that the patient was considered moribund. I had asked Dr. Gerster to see her with me, to give counsel as to the advisability of a high amputation, but by the time we saw her Dr. Gerster considered her death within a few hours to be almost certain,

and believed that any operation would probably be terminated by her death on the table.

I then turned to streptococcic antitoxic serum as a last resort, and injected $12\frac{1}{2}$ c.c. of Gibier's preparation, following this by vigorous stimulation by the rectum and under the skin. Twenty-five minutes after the antitoxic injection some flushing of the face was noted. In three hours the patient received another injection of $12\frac{1}{2}$ c.c., and one-half hour later a distinct flushing of the face again was apparent. There was twitching of the right side of the mouth, and the shrieks of the patient were incessant, though she was unconscious, could not swallow and could not be aroused. Next day—December 19th—the only apparent change was rapid emaciation. The temperature, too, began to rise. The urine contained hyalogramular casts. Two more injections were given. On December 20th the pulse-rate rose to 164 and was very feeble, and the temperature to 104° F. A loud pericardial murmur appeared, heard best at the base. Two more doses of serum were given.

For two days more the case went on in much the same fashion, the patient shrieking most of the time so that she disturbed the whole hospital, and breathing so frequently that the respirations could not be counted. Not until the evening of the 22d, five days from the onset of the severer symptoms, did she show the slightest real improvement. She then swallowed an ounce and a half of milk. On the following day, however, December 23d, after a short relapse, there was a distinct and rapid change for the better. Consciousness returned, there were two copious evacuations of the bowels without artificial aid, and nourishment was taken. The wounds now began to discharge and clean up. On December 24th a "diphtheritic" membrane appeared on the left side of the palate and uvula, other patches appearing on the buccal mucous membrane and on the lips. Cultures taken showed staphylococci and streptococci, but no Klebs-Löffler bacilli. Under local treatment the membrane was thrown off, leaving punched-out granulating areas which cicatrized. The pericardial murmur gradually vanished, and from this time recovery was rapid and unhindered.

It may be of interest to know that the father of my patient died a few years ago of septicemia following a glossitis caused by cutting his tongue in licking the flap of an envelope. She has a brother who lately has recovered from a malignant erysipelas starting in the nose.

In speaking of the apparent constitutional action of the serum, I would say that no distinct sign of improvement followed immediately upon any one injection, but for four days the patient's death was momentarily expected, so that I felt satisfied with the mere fact of her remaining alive. About 100 cubic centimeters of the serum in all were given. The blood was examined during the course of the disease by Dr. Mandlebaum, pathologist to the hospital, who reported no culture.

I beg you to note that I do not assert that this young girl was saved from certain death by the serum. I admit that she may even have recovered in spite of it; still, no man who saw her at her worst can help feeling that if he had to deal with a similar emergency the patient should have a chance for life with the serum rather than without it.

Recently I operated again on this same patient because of a sinus which developed at the site of the old scar with pain and fever. The serum was given a number of days before operation, with the result that her temperature fell from a daily maximum of about 100° F. to normal. Just before operation, $12\frac{1}{2}$ cubic centimeters were injected and the old scar widely opened. The discharge from the wound taken on the operating-table yielded a culture of staphylococci, but *no streptococci*. I removed a small sequestrum, and apparently having made a perfectly clean wound by the excision of the entire old tract and its cicatrix, I made an attempt to treat the wound by the Schede method of so-called organization of moist blood-clot. The experiment proved a failure, phlegmonous inflammation necessitating the removal of the sutures and the packing of the wound. It is interesting to note that now the discharge yielded a pure culture of streptococci. There were violent constitutional symptoms, with pulse-rate of 160, and temperatures to 104° F., but with absolutely no sign of cerebral disturbance. Convalescence was rapidly established. The local application of anti-streptococcic serum was once employed, and the wound surfaces certainly looked better the next day, but because of the ramifications of the wound tract this was discontinued since the experiment could not be satisfactorily carried out. It is my intention to try some other experiments with the local applications of the remedy.

Concluding, now, I will try to sum up the matter of serum-therapy in suppurative disease. To begin with, I believe that there is such a thing as immunity more or less complete from certain forms of suppuration. In Gould's "Year Book,"²¹ under "General Surgery," I find an editorial note as follows: "On the face of it, it seems improbable that there is any such thing as immunity, natural or acquired, to pyogenic infection. So far as immunity to *all* kinds of pus-producing infection goes, there may be some truth in this statement, but when one remembers that in laboratories where antistreptococcic serum is made animals are unquestionably rendered immune to certain kinds of the most virulent pus-producing organisms, one is obliged to acknowledge that there is such a thing as immunity, and that in the future we may hope for an increasingly great degree of certainty in the use of immunizing agents in surgery. I believe.

that the time is near when it will be common practice to make the attempt at immunization so far as possible immediately *before* surgical operations are undertaken, the period of immunity probably being very short."

As to the cure of cases in which sepsis already exists, it must be remembered that remarkable and unexpected recoveries are continually occurring, and that these recoveries are more apt to be published when they follow the administration of some new and fashionable drug or the application of some strange or sensational method. It is also, I fear, a fact that reports of many unsuccessful cases which might be very suggestive never see the light. We shall be obliged to wait until the mass of testimony is very great, perhaps even until the thing has been overdone and the pendulum begins to swing backward, before a true value can be placed upon serum-therapy in surgery. In the meantime, it is my opinion that the remedy is well worth trying, though never to the exclusion of what I may call legitimate surgical measures.

In no case which came under my observation have I noted any ill effect which could be ascribed to antistreptococcic serum, except, perhaps, an occasional smart urticaria. Indeed, in two of the cases here reported albuminuria disappeared, though this is one of the symptoms said to be caused by serum injections. It is well known, however, that evil has followed the use of antitoxin and of serum. Roger says that if filtered fluid is used the chance of accident is very slight. It seems that certain horses produce serum, the use of which may be followed by joint pains and swellings, adenopathy, enlargement of the spleen, purpura, anemia, nephritis, and other unfortunate sequelæ. It also seems as if death had in some instances been caused by the serum. The untoward effects are usually reported as having followed the injection of diphtheria antitoxin, but this observation may be due to the fact that the total number of cases treated for diphtheria is vastly larger than the number of cases treated for other septic disease. We must also distinguish, if possible, between the effect of the sepsis and that of the remedy. Yet, even if it be conceded that certain ill effects may occur, it means only that if serum-therapy is worth wider application the product must be further improved and its effects better understood.

THE DESTINY OF VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASES.¹

BY C. LESTER HALL, M.D.,
OF KANSAS CITY, MO.

SO FAR as this occasion is concerned, it matters not whether we accept Cohnheim's theory that "the only cells capable of originating neoplasms are those sequestered during embryonic life," or, with Williams, believe that "neoplasms are of intrinsic origin, due to a modification of the formative process by abnormal forces generated within the body, rather than extrinsic, due to inflammation or the intrusion of micro-organisms," or favor the more recent idea of the bacterial origin of all malignant growths. The fact confronts us that of all organs none is more prone to take on malignant degenerative processes than the uterus. Exposed as it is to so much irritation and injury incident to menstruation and mishaps in early girlhood, and those disturbing causes of mature womanhood—the marital relations and the traumatism resulting from childbirth, with constant irritating discharges setting up perverted cell action, it is not surprising that this nesting organ of all mankind should so often be the point of election for malignant degeneration.

The achievements of pelvic surgery by the vaginal route, with its immediate low mortality, has stimulated surgeons to extirpate the uterus for divers conditions, without, I fear, a just regard to ultimate results. Certainly in non-malignant conditions the removal by the vaginal route promises much in the way of completeness and lessened shock, for "benign tumors remain local, but the malignant types penetrate into the neighboring tissues and destroy them, and the tumor germs, being carried off in the blood and lymph, give rise to metastatic or secondary neoplasms in all parts of the system. Metastases have essentially the same structure as the primary tumors, and are found either in the vicinity

¹ Abstract of a paper read before the Section on Gynecology and Obstetrics at the Forty-eighth annual meeting of the American Medical Association, Philadelphia, June 2d, 1897.

of the latter, that is, in the region supplied by the lymph and blood which comes directly from the tumor, or in distant organs, after the tumor germs have passed through the heart. It is characteristic of tumor metastases, especially those from really malignant tumors, to go on growing indefinitely. Normal tissue germs do not have this peculiarity." (Tillman.)

Senn says: "Glandular carcinoma is followed at an early stage by regional infection. The lymphatic glands nearest the organ affected in the direction of the lymph current are usually involved first, when step by step, successive glands are implicated, until the entire chain of glands has become infected. Secondary tumors are subject to the same degenerative changes as the primary. The glandular tissue is completely removed in the lymphatic glands by the substitution of tumor tissue." He further speaks of "a wide zone of infiltration," and says that Virchow pointed this out several years ago, and that Waldeyer described it as an inflammatory zone, because he found in the connective tissue numerous small cells. "Infiltration tissue consists of leucocytes and young epithelial cells, which, like the leucocytes, wander by virtue of their ameboid movements into and along the connective-tissue spaces. Carcinoma of the alveolar type may develop within the cervical canal, and destroy the neck of the uterus before it is discovered, or in cancer of the body of the uterus, the cervix may become constricted, causing retention of the secretions (hydrometra), or the body of the uterus may be well nigh destroyed before the cervix is attacked." Lymphatic infection is found in the lumbar, retroperitoneal and inguinal glands. "Occasionally there may be found an isolated nodule of cancer higher up than the apparent edge of the disease. Whether this is due to lymphatic infection or to multiple cancer formation is an undecided question." (Warren.)

"Examination of the retroperitoneal lymphatic glands in suspected carcinoma of the uterus should never be neglected. In the great majority of cases the surgeon has to deal with carcinoma after regional infection has set in, and when the disease has advanced too far for a successful radical operation." (Senn.)

The last quoted authority also says: "The greatest progress in the treatment of carcinoma will have been made when we are placed in possession of an *infallible* means of early diagnosis." This was said in connection with carcinoma in general. Difficulties multiply when we consider carcinoma of the uterus, and there are no means of overcoming the obstacles presented. The hidden location of the

organ, the secretive and natural disinclination of women to communicate even to their nearest friends any suspicion entertained that all is not well are barriers which will require the education of many generations to remove. The average woman is so ignorant of her own organism that she is incapable of differentiating between the normal and the abnormal. She begins early in her womanhood to expect the "the change of life." Allured by the dangerous and false teachings of the mother who tells her that irregular flow is not uncommon, and that she must not be alarmed at this, or even at an offensive discharge, she keeps her secret, in blissful ignorance of the progressive degeneration which has overtaken her. When at last forced by failing strength and pallid cheek to consult her physician, the discovery is made that the diseased process has destroyed the cervix, that the lymphatic pelvic glands have become infected and that the broad ligaments and peri-uterine tissues have been invaded, and little hope of relief remains, either by palliative or radical measures.

Despite statistics (which too often are deceptive) showing many apparently permanent cures, on high authority we are forced to the conclusion that most cases of uterine cancer presented are inoperable, at least, by the vaginal route. With these discouraging conditions confronting us, and bearing in mind the limited field of operation, the accepted infectiousness of cancer tissue, and the possibility of the transference of living tumor cells during an operation, coupled with the impossibility of removing in many cases *all* of the diseased structure, we are forced to admit that the removal of the uterus per vaginam for malignant disease is, in the majority of cases, a doubtful expedient. Complete cures are rare, even when the carcinomata are extirpated very early in their course. As a rule, one recurrence follows another until the patient succumbs to general exhaustion.

Gross long ago claimed that in cases of malignant disease of the mammary gland it was absolutely essential to remove with the gland all of the axillary fat and lymphatics. In cancer of the uterus we have, in a great degree, a parallel condition to deal with, but the narrow vagina and the danger of invading other important organs and structures precludes the possibility of completely removing by the vaginal route all probable diseased tissue. In view of the opinions of some of the leaders in medical thought, we are compelled to look further for other and better methods of procedure in dealing with malignant disease of the uterus. It is probable that any plan of complete extirpation will be found inadequate in a large percentage of cases, but that

method which permits of the greatest opportunity for inspection of the diseased uterus, adnexa, and infected glands, and furnishes an opportunity for a more complete removal of all diseased structures, both primary and secondary, must ultimately become the operation of election.

The dexterity which has characterized American surgeons in abdominal section for the total removal of the uterus and appendages, leads to the belief that in the near future vaginal hysterectomy for malignant disease will be restricted to those rare cases in which women present themselves in the inception of the disease, and before secondary infection has taken place. It is the opinion of the writer that the more radical operation known as the Clark method will supersede vaginal hysterectomy for cancer. By this abdominal method of total extirpation of the uterus and adnexa the posterior peritoneum and all glands at the bifurcation of the iliac vessels are brought into view and removed whether infected or not. We are thus enabled to go beyond the inflammatory zone and to remove diseased glands which are not within reach by the vaginal route. The bladder, the ureters, the rectum and all other important structures are brought directly into the field of vision. Thus directed, the hand of the operator does thorough work, and the poor sufferer has done for her the best that the science and the art of surgery can offer. The objection urged against this operation—that it is tedious, that too long exposure results, that prolonged anesthesia endangers the patient's life—will all be overcome by that practice which makes perfect.

A STUDY OF THE SYMPTOMATOLOGY OF THE NEURASTHENIA IN WOMEN.

BY LOUIS FAUGERES BISHOP, M.D.,
OF NEW YORK.

THIS subject is considered on account of its important bearing upon almost all cases of disease occurring in women, but because neurasthenia is studied in this connection I would not have it inferred that men are less liable to its manifestations. To begin with, "neurasthenia" must be considered a condition, which only in a certain proportion of cases reaches the dignity of a separate disease. It has been of special interest to me because I have approached it from two standpoints which might almost be defined as negative and positive. I have studied it as a practitioner, devoted particularly to the cultivation of internal medicine, and on the other hand, as a worker in a very large neurologic clinic where neurasthenia naturally is a luxuriant growth.

Exhaustion, anemia, and poisoning of the nervous centers have been named as the three primary causes

of neurasthenia. Bossier of Paris regards it as an attenuated melancholia. We must never lose sight of the fact that the causes of the condition in most of our cases are concealed by the patient. Altogether too few cases in our experience are traced to causes which we are confident are actively operative. It is the rarest thing indeed for a woman to acknowledge the habitual excessive use of alcohol. The same is true of other drugs, and of vicious habits. Some investigators seem to be better able than others to discover the truth in these respects, but certainly the number recorded is suspiciously low. Some of the patients take their drugs in the form of a proprietary mixture with an innocent name, and are not conscious themselves of the cause of their nervous exhaustion.

It is probable that uterine disease is a comparatively unimportant element in the causation of neurasthenia. Much more frequently neurasthenia gives rise to uterine symptoms. The error of treating such cases as primary cases of pelvic disease, has been almost too often emphasized to make it necessary to dwell upon it at the present time. In neurasthenia from some cause the nervous system seems to suffer deterioration of power as a whole rather than develop a definite local lesion. Although no lesion is discoverable by any pathologic examination so far made, it is probable that there really is a failure of nutrition of the whole nervous system.

To the neurologist, neurasthenia as a diagnosis is too often a nosological dumping-ground for everything that is not clearly something else. There are a few fairly defined types that in spite of the surprising variations in surface symptoms will retain their identity. On account of this versatility of symptoms, we must in a definite way go deeper than merely sorting subjective sensations for a basis of classification. Just as the botanist lays down a certain fundamental basis for the classification of plants, and neglects color, size, and latitude in the application of a definite system, so in the classification of neurasthenia we must base our diagnosis upon the character, surroundings, and life history of the patient, just as much as upon the particular coloring or form of the disease at the time when observed. The practical advantage of this more fundamental study is that it suggests lines of management which will correct in a degree the primary cause of the disorder.

A typical case presenting itself for treatment shows a woman between the ages of twenty-five and fifty, fairly well nourished, somewhat anemic, who complains primarily of a subjective sensation of nervousness followed by a train of symptoms that is different in every case. Fairly constant is the complaint of pain in the top of the head, sleeplessness, loss of

appetite, and subjective sensation of tremulousness, but the most characteristic of all is the neurasthenic manner—the abnormal concentration of the attention upon symptoms—and their exaggeration. The patient delights in recounting the minutest details, and yet seems, in a sense, rather to enjoy a concealed happiness or pride in her condition. Neurasthenia is essentially a debility. Its importance to the individual is very great indeed. A confirmed neurasthenic is literally unable to stand the ordinary hardships of life. Of this the patient is thoroughly conscious, and is constantly seeking some explanation in the presence of some more definite disease.

A good synonym of neurasthenia is pathologic fatigue. The parallel of physiologic fatigue with neurasthenia is very close. The neurasthenic, however, is tired in the morning and feels better toward night. Curiously enough, an early stage of neurasthenia is marked by a lack of the sense of fatigue, which has been happily termed fatigue anesthesia. The danger of this condition is easily apparent, as the patient unconsciously goes beyond the limits of physiologic fatigue.

The existence of neurasthenia as a local disease has been suggested by Huchard of Paris under the term of local neurasthenia. With the number of manifestations of neurasthenia already on hand, it is rather cruel of Huchard to suggest another difficulty. If he deprives us of diagnosis by variability, we may well wonder what ground we have to stand upon. However, it is entirely improbable that neurasthenia would manifest itself in one direction alone for any length of time.

Neurasthenia varies much in type with age. The youngest cases verge into a type of acute simple anemia while the older cases approach the type of chronic diffuse nephritis. This may not have impressed others, but unconsciously I have found myself differentiating these various diseases in the younger and in the older group. Then there is the neuralgic type, usually differentiated from real neuralgia by the mobility and atypical location of the pain. Patients suffering from the nervous type complain most prominently of a general sensation of nervousness often described as “inward chills.” The tendency in all forms is to exaggerate the symptoms, and one who is not on the lookout is often enough deceived. These patients come with a tale of constant abject misery lasting for a month at a time, of sleeplessness and absence of appetite, when, if you happen to observe them when going about their ordinary occupations, they show no evidence whatever of real suffering.

When we come to those patients in whom the element of nerve depression or nerve exhaustion

seems to be a more prominent factor in the case than any other disease, we may divide the patients into two classes—those in whom there is an accompanying physical disease, and those in whom the physique seems to be fairly good and the nervous system itself almost alone at fault. The latter are the more chronic cases, and often enough verge closely upon the domain of hysteria, or even insanity. The former class of cases are the typical ones, most frequently met with, and those of most interest to the general practitioner.

There is a class of border-line cases in which the patients suffer from pains in the limbs and body, such as may very well be due to rheumatism. Definite rules for differential diagnosis cannot be laid down. Each case must be studied by itself. There is no doubt, also, that many symptoms in middle-aged persons caused by gout are mistaken for neurasthenic symptoms by neurologists.

An interesting symptom is described by Grasset of Montpellier under the name of amyasthenia, which he describes as a sensation of sudden fatigue. The symptom of the sudden giving out of the knees in neurasthenics is familiar enough. This symptom can receive fresh interest from this very good name. Laziness is more often a real disease than is commonly imagined; it simply means in those cases diminished evolution of the higher nerve energy.

Like hysteria, though in a less degree, neurasthenia resembles or presents the symptoms of many organic conditions, but there is this difference: the hysteric person often gives a clear and distinct imitation, while neurasthenia presents, as it were, a wavering and shadowy picture of real disease.

The differentiation between neurasthenia and insanity is not difficult in actual practice. After organic disease has been eliminated from our diagnosis, as far as possible, in a large number of cases there remain more or less definite manifestations of nervous disorder. Neurasthenia, however, is a condition which cannot always be diagnosed by exclusion because it is a condition which may accompany almost any disease. The number of marked cases of neurasthenia is not very great. Its very long course and the persistency with which the patients seek medical advice makes the disease appear so common. The milder types on the contrary, are very frequently met with.

It is absurd to call neurasthenia “the American disease.” No one can work in the large clinics and not be impressed by the existence of this condition among people of all nationalities. In fact, the worst cases we see are among foreigners. It is certain that among Russians, at least, the class of which we have such enormous numbers in New York, there are

found cases of neurasthenia which, in proportion to the organization of the patients, it would be hard to parallel.

The treatment of neurasthenia, like that of gout, must be summed up as an intelligent adaptation of well-known means to meet indications as they arise. It would, perhaps, be better to speak of management rather than treatment, as it covers hygiene and the control of the habits of life and thought, in addition to the administration of drugs. In the management of these individuals it is absolutely necessary to gain their confidence; and a great advantage is gained by having them understand to some degree the nature of their trouble. It has sometimes seemed useful to explain that the nervous system as a whole, the spinal cord, the nerves, and even the brain itself, is in an atonic state; that this debilitated organization is liable to be affected by the slightest causes, and that the symptoms will correspond to the sensation usually associated with stimulation of that part of the nervous system. Fortunately, many neurasthenic patients are people possessing mental power above the average, and when once they have been taught to corollate their many-sided symptoms with the general cause, and to disbelieve in the presence of constantly changing organic disease, they will have reached a much more hopeful plane from which treatment may be commenced.

A very trying feature in many cases is their chronicity. Many patients recover to a certain point so that they are fairly comfortable and are able to carry on their occupations, and yet they have not attained sufficient independence of mind to get along without medical supervision. These cases hang on in a physician's practice often for months and years. The physician feels from a strictly medical standpoint that he is no longer useful to such patients, but that the moral support derived from their occasional relation of symptoms is just as necessary to them as cod-liver oil to a consumptive, or nitroglycerin to a nephritic. Some of these patients persist in visiting a physician long after he has refused to give them any more medicine or treatment, and they talk themselves into a comfortable frame of mind and go away greatly benefited, there having been no treatment whatever. This moral support that neurasthenics demand is often very tiresome to one who is interested in pathologic conditions, but if the patient is treated with absolute honesty, it seems to be a legitimate part of one's medical work. These patients have put themselves under one's care for a condition that is just as much a disease of the mind as anemia is a disease of the blood. Physically, you have corrected, as far as you consider possible, the ailments that demanded drug treatment, and which

may have been the origin of the trouble, but the patient is left in a condition in which he is unconscious of his cure, or rather, in which the disease has been transferred to the mind. If, at this stage, we throw these people off, they invariably try all kinds of treatment, and are pretty sure to undergo medical or operative interference that will set up some new physical pathologic trouble. These patients must be accepted, and so long as they remain patients, must be given moral support. Some of these prolonged cases go on to complete recovery.

Thus, in that very severe and troublesome type, post-operative neurasthenia, we must labor to divert the channels of thought and erect a barrier of reason against any future idea of local disease—a task not made less difficult by the constant willingness of men devoted to pelvic medicine to continue an attempt to reach the base of the brain with the speculum and curette. These cases of post-gynecologic neurasthenia must, of course, be distinguished from essential organic disease only after a thorough examination by one especially trained in that department of work. To quote cases would only be to repeat the experience of every physician, but the subject has been newly impressed upon me by a recent experience with a patient in whom, after endless consideration of local disease, one eminent surgeon had removed the ovaries, and another later on had insisted that hysterectomy would be the only salvation, I finally concluded that the pain was chiefly of psychic origin and insisted upon her removal from bed and transference to the seashore. The result was more than the most sanguine person could have hoped for. The improvement was so great that the patient herself became convinced that her pain was not due to local disease, and agreed to discard treatment and resume, as far as possible, her ordinary life. The pain was much modified in character and frequency, and she is no longer a helpless invalid. Unless a diagnosis of neurasthenia had been made, she would still be under treatment for supposedly local lesions, thus adding misery to a condition bad enough in itself.

Of the gastro-enteric origin of neurasthenia, in certain rare instances, there can be little doubt, but the explanation does not cover the ground in a majority of the cases, and the expectation of curing such patients by some particular combination of drugs supposed to have an extraordinary antiseptic power, will lead to disappointment.

J. J. Putnam of Boston recommends the psychical treatment of neurasthenia, which consists chiefly in making the patient master the disease by exerting her reason and will. The wonderful results obtained by certain physicians are due to their personal influence upon the patient. The absence in the

American constitution of a craving for amusement, such as characterizes the French, for instance, leads to a neglect of sufficient recreation, and in that way exaggerates the results of overwork, and the tendency to neurasthenia. There has been a good deal of improvement in this respect since the use of the bicycle has become general, and since other outdoor recreations have become so popular, but the fact remains that in America we need to realize that recreation is essential to the performance of good work.

It is doubtful whether many diseases run their course without the neurasthenic element being more or less present, so the physician should estimate, discount, and treat it in every patient. I have a strong conviction of the importance of making such allowance for the neurasthenic element in all cases of disease of whatever nature; that it is necessary to realize in careful diagnosis that the patient herself under the influence of disease is capable of displaying an indefinite number of symptoms which have their origin, not in the disease, but in the patient under the stimulation of the disease. This is the case in many of the so-called reflex symptoms, that is, whenever disturbance of one organ is reflected from another in symptoms characteristic of the latter. In persons prone to neurasthenia, the whole nervous system reflects symptoms from any local stimulus, and on account of its variety of powers of giving rise to symptoms, the picture is a most confusing one. It is just as if a lamp were hung among a lot of mirrors. It is very difficult indeed to immediately pick out the lamp from among all its reflections. The immense importance of training in the objective examination of disease is here manifest; if we use our eyes alone we will be mistaken. A reflection of the lamp is seen, but the sense of touch immediately differentiates the warm lamp-shaped object from the cold, smooth surface of the mirror. Then again, if a shade be interposed between the lamp and the mirror the lamp retains its light, but the mirror loses its reflection. Or, if we move so that the line of reflection falls outside of our line of vision, the light from the lamp remains, but that from the mirror is lost. In the same way, in examining and testing the symptoms of patients, we can with care and thoughtfulness differentiate the real symptoms of the disease from the reflected symptoms of its accompanying neurasthenia.

Children Without Arms.—It is reported that a child without arms has been born recently at Laporte, Ind. It is strong and will live. This is the second child without arms born to the parents, the first being now three years of age.

THE INCREASING CONSUMPTION OF ACID FOODS AND DRINKS.¹

By W. T. ENGLISH, M.D.,
OF PITTSBURG, PA.

It is attempted in this paper to establish the following principal points: (1) That there is an increasing consumption of acid foods and drinks; (2) that increasing demand for acids is fostered by the artificial customs and habits of modern life; (3) that the appetite so acquired and indulged is contrary to physiologic law.

The consumption of acid fruits and vegetables in recent years has been and is now promoted by the fact that these foods are procurable at all seasons—in the extreme cold of our winters as well as the heat of our summers. Obedient to the all-powerful dictum of the spirit of intellect, temperatures are modified and our soil yields the products of different climes at any season. The seductive influence of the presence of the product cannot be questioned. Add to this continuous supply the advantages of celerity of transportation, and the sequence is that very few of the vegetables and fruits hitherto regarded as natural summer products are absent from our tables in mid-winter.

It would be impossible within the scope of this paper to refer to the individual products concerned in the ever-increasing list of acid foods consumed in this country. Let a few suffice. Tomatoes, which depend for their flavor upon a peculiar acid (*acidum lycopersicum*), have rapidly grown in favor, until, from comparative obscurity, they have reached the head of the list. It has been estimated that during the years intervening since 1890 this vegetable has multiplied in production ten times.

Each week during 1885 it required twenty-five carloads of lemons to supply the city of New York. At the present time the daily demand exceeds that amount. This is true of other cities, and for the most part the country demand is proportionately augmented. Oranges are supplied in about the same relatively increased quantity. Limes are the most keenly acid of all fruits. Almost unknown outside the fashionable drinking halls five years ago, to-day they are a commodity. They are imported pickled as well as fresh, and the bottled juice comes to this country in large quantities from the West Indies. Congress has recently placed a special tax upon this fruit, because of its large importation. The grateful acid of the rhubarb leaf, in conjunction with binoxalate of potash, with the malic acid contained in gooseberries, currants, cherries, plums, apples, and pears, adds to the acidulous tide.

¹ Read before the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, Philadelphia, June 3, 1897.

Recently it was learned from a large commission merchant that apples, to be salable in our markets, must be decidedly acid. Sweet apples are employed only in making cider and vinegar. Some varieties of the small sweet fruit have almost disappeared, and their places have been filled by those that are tart enough to please the present acid taste. It is rare to find the mulberry, the black currant, the sweet cherry, or the sugar-grape. The almost innumerable grafted fruits, usually more acid than the seedlings, are extensively cultivated, and to the exclusion of the original stock.

It is claimed that the cheapness of sugar permits the consumption of acid fruits which otherwise would be distasteful. The ingenuity displayed in bringing acid into a condition to make it palatable serves to prove the increasing tenacity of the acid habit. Sweet and neutral vegetables, as beets, cabbage, lettuce, etc., are often rendered acid in order to give to them the much desired sour flavor. Forty thousand tons of cucumbers are raised and eaten within the limits of the United States each year, and this affords an excuse for the employment of about 1,000,000 gallons of vinegar and acid sauces or condiments. The large pickle factories that began with the decade have been reinforced by new establishments and additions that double their capacity for sending out acid products. The demand for piquant sauces has caused a large special industry to arise within the twelve years now ending. Meanwhile the home culinary department has augmented its capacity as to quantity and variety. A considerable amount of salicylic and boracic acid contributes to the preservation of fruits.

To visit the modern pie-bakery is to learn of human ingenuity employed in a most peculiar service. Boston boasts of a pie factory which turns out 1000 pies per hour, and the machinery seems to know its business better than the people who eat the pies know theirs. It is startling to hear of the remarkable pie-eating tendencies of the people of this country. A baker recently estimated that the American stomach is tortured weekly with 13,000,000 pies. Mineral and vegetable acids flavor the contents of eighty per cent. of these pies.

However formidable may appear the subject of acid consumption as already presented, the diabolic ingenuity of the *chef de cuisine* as he appears in public restaurants, hotels, clubs, railway dining-cars, steamers, etc., eclipses all. Wherever you dine—at Delmonico's, or at the humble restaurant where you can get three dishes for 25 cents—the foods are rarely of the alkaline character that nature intended. Especially is this so in the more pretentious dining-halls. From the tomato soup that is full of floating

sour and indigestible ornaments, and fish with sauce enough to constitute a dinner in itself, through the roast and to the final black coffee, there is a blend of an infinite variety of incompatible acids, flavors, and liquors. It is indeed the exception to find an ambitious caterer willing to serve an article before it has donned an acid habit. The natural flavor is so disguised that the palate of the connoisseur is taxed to recognize it.

Acid foods and drinks menace the urbanities and amenities of modern social life. A woman is to be commiserated who is invited to a *récherché* dinner of her social class, as furnished by the up-to-date caterer, if she has not the moral courage to decline. To attend such a dinner is to indulge in a feast of sours and a flow of acids from the first to the last service upon the *ménu*. If averse to acids, she nevertheless must yield a tranquil servitude and graciously accept the hospitality, or, by adopting the perilous liberty of declining some of the intricacies, brave the possibility of social ostracism. All the civil asceticisms of the nineteenth century may congregate on the *ménu* upon such an occasion, and yet may appear as a poem to the *chef de cuisine* and all others concerned. The modern fashionable women, anxious to outdo each other, are rendered not only somatically, but also psychologically, ascetic on the appearance of a brand-new, unexpected, and never-heard-of-before dish on their rival's table. Extraordinarily, it may have the appearance of perfection, but it will prove an incarnation of acidity and fermentative microbes. Never less than fifty incongruous elements combine on such occasions, with alarming disregard of consequences.

These dissipations are augmented on festive occasions. The learned ignorance of the *chef de cuisine* has its best opportunities at public places and at grand events. The chemist of the culinary department under such circumstances takes advantage of the chemist of the *prima via*. To all the acid inventions that can be placed upon the *ménu* are added the sherbets and the lemon and orange ices. The claret's purple tide mingles with the frolicsome vapors of champagne, in accordance with the wine-bibber's fancy. The punch-bowl, with its capacious supply of acid drink, has reappeared from comparative obscurity with an intensity of purpose that adds to the ascetic view. Beer, wine, or spirits join in the after-dinner tumult. The coffee cocktail and the Roman tea with spirits are among the most popular inventions of the enemy, and are regarded as heavenly twins by true Bohemians. But the list reaches out and defies limit, and whether the flavor be sweet or sour, there is hidden somewhere the acid ingredient, which will be recognized by the *prima*

via, even if it escape the observation of the senses. Thus, in all departments of social, private, and public life the *chef de cuisine* is making himself felt. Our own inclinations have been subjugated so that we require in one form or another in our homes some of these acid products or compounds.

Probably the first symptom of acid desire appears in the taste for the aerated table waters which are everywhere available. The realm of acid ingesta geometrically expands when we enter the domain of drinks. In the drinking-halls the casual observer cannot fail to be impressed with the tendency to indulge in acid beverages that are of recent origin, while those of more or less remote popularity still occupy their position as to quantity consumed. But if the question were asked to-day as to what is the national drink, it would be answered by the fizz of the soda fountain. We can all remember that only a few years ago the soda fountain was a rarity, and the variety on its list of drinks could be counted upon the fingers of one hand. To-day every hamlet and town in the country has them in numbers equal to their confectionery stores and apothecary shops. In the cities they are enthroned in every available locality, where hundreds hourly pay obeisance, and the variety of their flavors is only limited by the mental elasticity of the presiding genius. Foreign countries know little about the American soda fountain, but it increases the acid consumption one hundred fold in this country. The most profitable and largest part of the druggist's trade to-day is that of the product of the soda fountain. Mineral and vegetable sours contribute to the tide of acids which enter the stomach from this source. The carbonic-acid gas is swallowed and not inhaled. The late John Matthews of New York first introduced the idea of charging water with gas. This is supplied in immense tanks to the beer brewers to inflate their beer. The drums of compressed liquid gas for carbonating soda water are furnished and refilled by the brewers. In this and some other respects the soda fountain is a cross between the saloon and the restaurant. Small lunches are supplied at some soda counters, consisting of hot tomato and clam bouillons, beef tea, cocoa, chocolate, coffee, tea, ice-cream soda, cake, crackers, etc. The most common demand, however, is for the acid-flavored drinks, including mineral and vegetable acids, with water charged with carbonic-acid gas. Ice-cream soda has grown very popular within the past two years, and women and children throng about the soda counters during the summer to gratify the desire for this cool and acidulous drink. Bottled drinks of all kinds which are non-alcoholic are offered by the apothecaries and grocers, and have become

a large and recent adjunct to the acid-distributing trades.

Thus it appears that the vegetable products are prejudiced to the acid side. The culinary department adds its effective ingenuity to educate our tastes in the acid direction. Our drinks are rarely alkaline. All this obtains, too, in spite of the fact that acids are naturally rejected in early childhood, and only rendered tolerable or agreeable by acquired appetite. The increased consumption of acid foods and drinks cannot be accounted for by the increased population, for it is out of all proportion to its growth. Indeed, our population during the last decade has remained almost stationary, while the acid demand is increasing in geometric ratio each year. The consumption of acid foods has increased out of proportion to all other foods, and the amount of acid drinks ingested has doubled every year since 1890.

This extending and increasing appetite for acid foods and drinks is evidenced by the self-conscious need that many feel for anti-acids to counteract acidity of the stomach. Wherever sour drinks are sold there are also the anti-acid, as bicarbonate of soda, magnesia, etc., on hand for the accommodation of those who cannot uninterruptedly continue the acid pace. Again, medical men will admit that the trend of therapeutics is forced, however unconsciously, into the anti-acid and anti-fermentative realm. This is not only because of the introduction of sour acids, but is also due to the fact that the acid conditions favor the development of micro-organisms and promote fermentative conditions in the body. These micro-organisms are always more injurious in their effects than the acids that are used as foods and drinks.

The various modifications of the digestive function incident to the excessive use of acid foods and drinks are already with us, and the acidulous habits of the body mark a stage in civilization. These facts, stated in connection with the estimates above made, should satisfy all that the acid appetite fostered and gratified is contrary to physiologic law. It may further be argued, however, that the acids employed are not only unfavorable to proper digestion, but that they directly and indirectly modify the chemico-composition of the blood and bodily fluids, and must therefore seriously interfere with the somatic functions. It will be remembered that all the digestive acts are performed normally in the presence of alkaline media, except in the stomach. The normal percentage of hydrochloric acid in the stomach is one part to four thousand of stomach fluid, and this proportion of acid is sufficient to put an end to the alkaline action of the saliva on starchy foods. Another

duty devolving on the hydrochloric acid is to check organic fermentation and putrefactive changes by destroying the specific microbes by which they are induced. To accomplish its office in the most perfect manner possible, it must be carefully proportioned, for any excess or diminution, however slight, despoils it of its capacity and interferes with the succeeding digestive acts. The common habit of the American stomach is the sour or fermentative habit. At no time in the history of medicine has the stomach demanded such a generous special supervision as to-day, and in no country equal to our own. If the difficulties were limited to this organ, a thorough system of lavage and special treatment might terminate the trouble; but the succeeding acts of digestion are imperiled. Sufficient acids and ferments in the stomach continue to act upon the pancreatic juice and the bile to despoil them of their alkalinity and thus render their action of no effect upon a portion, if not all, of the food ingested. The intestinal juice is so decidedly alkaline that it will neutralize a large amount of acid before yielding up its alkalescence, but it is frequently compelled, as are the other fluids, to call upon the reserve alkaline elements of the body. Thus, not only the digestive fluids are depleted of their alkaline elements, but the alkaline bases and salts are reduced in the fluids and tissues of the economy. The ingestion of acids increases all alkaline secretion. Saliva, pancreatic juice, bile, and intestinal juice are all alkaline in their normal state. Nature has intended that the ingestion of food should increase alkalinity. After a wholesome meal of proper foods there is an increased alkalescence of all bodily fluids. The alkalinity of the blood is the measure of its germicidal capacity, and if it is normally alkaline it has the power of increasing immunity against infectious diseases.

Fodor says: "Rabbits, in whom either the blood is more highly alkaline or in whom the alkalinity increases under infection, offer greater resistance to anthrax bacilli than those rabbits whose blood is only slightly alkaline." Many authorities agree that the alkalescence of the blood prevents disease. Laboratory analyses and clinical observations are corroborative of this view. It is well established that reduced alkalescence of the blood-serum deprives it of its coagulating potency in proportion to the degree of alkalinity. The red blood-corpuscles contract in the blood-serum of reduced alkalescence. Under such conditions the blood deepens in color in the arteries. The cyanotic appearance of the surface of the body, and especially the purple hue imparted to the lips in many cases, may be accounted for by the condition of the corpuscles. Moreover, it must be remembered that the red blood-corpuscles are the

servants of the respiratory apparatus, and by this interference with their office there must be a reduction of the efficiency of the functions of respiration. The sympathetic nervous system is influenced by hyperacidity, and causes in turn a general functional derangement of the organs, notably the heart. The intellect is temporarily confused, and in some this confusion reaches out into incoherence of thought and action. The moral influence of these perturbed conditions of heart and mind extend to and pervert the imagination, and in extreme cases leave their permanent impress. The coexistence of somatic and psychologic asceticism can no longer be ignored.

CLINICAL MEMORANDA.

THE LOCAL USE OF HIGH TEMPERATURE WITH DRY HEAT IN THE TREATMENT OF RHEUMATOID AND OTHER DIS- EASES OF THE JOINTS AND TENDONS.

By H. C. WOOD, M.D.,
OF PHILADELPHIA;

PROFESSOR OF MATERIA MEDICA, PHARMACY, AND THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

IN the application of superheated air for the treatment of rheumatism and other diseases of the joints and tendons, my experience has been with the Tallerman-Sheffield apparatus as made in London. I had the apparatus in almost continuous use for seven or eight hours a day for about three months. A number of cases of rheumatoid arthritis were treated by it, though only four patients persevered beyond three or four treatments. Of these, Mrs. N., in whom the knee-joints were especially affected, received twenty-five *séances* of a full hour each. In the beginning of the treatment there was immediate relief, and until fifteen sittings had been given there was steady, though slow, improvement. After this there was a relapse and an increase of pain, so it is doubtful whether the woman was any better for the service.

Mrs. H., suffering from rheumatoid arthritis affecting the hands and knees, received twenty-seven treatments. During this time there were periods of apparently steady progress toward health, followed by rapid relapses. At the end of the treatment the knees were very much improved, though the hot applications had been made almost exclusively to the hands. The knuckle-joints were less swollen, and the hands more serviceable. Toward the end of the treatment the local hot-air baths produced immediate, and in some cases, alarming exhaustion. With the oncoming of hot weather it was evident that the general condition of the patient was made worse by the heat application.

Mrs. S. took eight treatments with some apparent benefit to the rheumatic joints, but marked increase of her debility. Mrs. McK. took eight treatments. At first there was some relief, but at the end of the course she appeared in nowise improved.

Of chronic rheumatism, not of the type of rheumatoid

arthritis, but resulting from acute attacks, one patient, Mr. C., received sixteen treatments. The joint affected was the knee. There was apparent softening of the adhesions, so that the false ankylosis was readily broken up, but this procedure was followed by great inflammation of the joints. The man finally discontinued the treatment because he did not believe he was obtaining any benefit. The results for good in this case must be considered doubtful.

In subacute rheumatism of the joints I have had experience with two cases. In one there was apparent cure after three treatments, but this was followed in two or three days by a violent relapse, for which the patient declined further treatment. One case of subacute rheumatism of the knee-joint, which had received no treatment before, rapidly recovered under the use of the hot-air bath and large doses of the salicylates and colchicum.

Of rheumatic neuritis, three cases were treated. In one, sciatica, such great aggravation of the symptoms followed the first treatment that it was impossible to get the patient near the apparatus again. In two cases of chronic type, four treatments were followed by great increase of pain. In one case, in which the nerves of the upper arm and the brachial plexus were involved, fourteen *séances* were followed by marked improvement, with increase of motion in the shoulder-joint and great improvement of the general condition. This patient, however, was also very carefully treated with counter-irritation, drugs, massage, etc., and it was not determined that pronounced good followed the use of the hot-air apparatus.

The results of the treatment with the hot-air bath in diseases of the joints themselves have not, in my experience, been sufficiently satisfactory to warrant the practitioner in urgently recommending patients to undergo the expense and difficulty of the treatments. It does not seem that the conscientious doctor can say more than that the remedy is perfectly safe and may be of service.

The fact that in my experience, and in that of others, the earlier treatments have been followed by an immediate acute paroxysm, would indicate that softening of deposits of urates, and consequent absorption of uric-acid into the system, may result. In most cases of chronic rheumatism, however, and especially of rheumatoid arthritis, as seen in this country at least, there is no distinct local deposit of urates. I have reason to believe that it is possible to affect the nutrition of the joints of the hand more than those of the feet; this fact, if indeed it be a fact, evidently being dependent upon the greater readiness with which a small joint can be superheated than can a large one. On the other hand, in cases of diseases affecting the tendons and ligaments, the results were very marked. In several cases of acute sprains the effects were immediate and pronounced. In one case of chronic inflammation following sprain of the soft parts of the ankle which had entirely disabled the patient for nine months in spite of careful medical treatment, complete restoration was obtained after six of the hot-air treatments. In two cases of disabling tenosynovitis in baseball pitchers, there was immediate relief of the pain produced by moving the arm, and a very few treatments

enabled the men to resume work. In one case of long-continued contraction of the wrist tendons and general distortion of the fingers, diagnosed by Dr. Weir Mitchell to be the result of gout, three treatments were followed by complete cure.

In using the apparatus, it was found that if the limb was lightly enveloped in patent lint, a temperature of 330° F. could easily be borne by most patients. We tried all temperatures in these treatments, but finally settled upon one ranging between 270° and 320° F. Of course, any carelessness in the use of the apparatus was liable to result in the production of severe burns, but those which occurred in my office were all at a lower temperature, and in the first use of the machine before the nurse had become thoroughly acquainted with the application of the remedy.

In my opinion, the local, hot, dry-air bath is of little value in rheumatoid arthritis; it has probably a field of usefulness in subacute gouty inflammations with deposits about tendons and their sheaths, or parts outside of joints, and is of great service in the treatment of ligamentous inflammations, and in tenosynovitis, whether of rheumatic or traumatic origin.

When the patient is heavily wrapped in blankets, it is possible to raise the general temperature several degrees as shown by the free sweating thus produced. The local bath is capable, without doubt, of relieving subacute or even acute lumbago and other forms of rheumatism in very much the same way that the free sweating by the general hot-air or water bath brings relief. There is not the slightest reason for believing, however, that the method acquires any further constitutional influence than has just been spoken of, and it seems an absurdity to suppose that it will distinctly affect the rheumatic diathesis, or in any other way prevent the recurrence of those relapses which in rheumatoid arthritis and chronic rheumatism are the destructive factor of the disease.

**A CASE OF EXOPHTHALMIC GOITER IN
WHICH, OWING TO PANOPHTHALMITIS,
THE ENUCLEATION OF BOTH EYES
IN SUCCESSION BECAME
IMPERATIVE.¹**

By JAMES A. SPALDING, M.D.,
OF PORTLAND, MAINE.

UP to April, 1895, Mr. A., a Dane by birth, had been perfectly healthy. He was then about thirty years of age and a hard-working and industrious farmer. On the 10th of April he had been working harder than usual, when he suddenly felt dizzy, and every object that his glance embraced appeared double. The lateral separation of the images was quite considerable, but he was sure that they were on the same level. On covering his eyes in succession, to discover if there was any difference in the sight which would account for the disagreeable diplopia, he found that the sight of the right eye was slightly blurred. On covering the right eye, he failed to see double, and the dizziness ceased. On covering the left

¹ Read at the Thirty-third Annual Meeting of the American Ophthalmological Society, Washington, D.C., May 5, 1897.

eye and trying to move about he felt nearly as dizzy as with both eyes open. He consulted his family physician, who sent him to an ophthalmic surgeon, who diagnosed paralysis of the internus muscle (as I later heard), prescribed iodid of soda, and directed the patient to wear a shade over the right eye to prevent the very annoying diplopia. A weak astringent lotion was also ordered on account of a well-marked inflammation of the lower conjunctival fold.

A few weeks later, the right eye, which previously had not projected in the least, began to bulge forward quite noticeably, but the diplopia was not so disturbing as before, since at about the same time the sight of this eye sensibly diminished. After undergoing treatment with the galvanic current the patient was told by the consulting oculist that nothing more could be done for the eye, and was advised to see his family physician, owing to other symptoms needing medical treatment. Enlargement of the thyroid on the right side was now quite evident.

The medical treatment then instituted, whatever it may have been, did not seem to be of much benefit to the patient's health, for the thyroiditis, with increased heart action, and protrusion and deviation outward of the right eye still persisted. The cornea, also, according to the patient's assertions, now became so gray and hazy that the sight was reduced to a minimum, although he could still see objects held close to the eye. The sight of the left eye remained perfect. Whether at this time the left eye protruded or not is impossible to say, but so far as could be determined it remained in its normal position. The difficulty in forming an opinion in this respect lay in the fact that the protrusion of the right eye was so great as completely to throw into the shade any displacement of the left eye.

Having been several months under treatment, without any benefit, Mr. A. consulted me in August, when I discovered the following conditions: The right eye was enormously protruded from the orbit, and the eyelids so much distended over the cornea as to remain immovable, despite every effort to close them. There was excessive chemosis of the conjunctiva, which surrounded the entire cornea with a dry, fleshy wall, as nearly as can be described. The cornea was very much dessicated, and in the center there was a small abscess. Hypopyon also was present. Oblique illumination seemed to show that the pupil was largely dilated, but this was difficult to determine with any accuracy owing to the haziness of the cornea. The cornea was quite insensible to touch. There was perception of light in all directions. The tension of the eyeball was increased.¹

The patient had been suffering for several days from intense pain in the eye and orbit. He could not sleep without the exhibition of large doses of narcotics, and the latter were contraindicated by his bodily condition. His

temperature was more than 100° F. night and day, and the pulse ranged from 130 to 160. The eye resembling one affected with panophthalmitis, and being rather timid about enucleating in that condition, I resorted to leeches to the temple, to scarification of the conjunctival folds, and to division of the external canthus. Finally, however, all these means failing to relieve the condition of pain and suffering, the eye was removed. On opening it, immediately after the operation, pus was found in the anterior chamber, as well as behind the ciliary processes on the temporal side, and in one separate focus in the vitreous, just as we see it in panophthalmitis following perforating injuries of the globe.

The result was very favorable, and the patient soon returned to his home. Careful examination before his departure showed well-marked swelling of the thyroid, on the right side chiefly, though moderate indeed in proportion to the enormous protrusion of the orbital tissues, which even after the removal of the eye pressed far between the commissure of the eyelids, preventing any attempt to close them except by actual force. The whole orbit remained then, and still remains, filled with hard, brawny tissue.

Thyroid extract was administered in small and regular doses for a long time, and being well borne was continued, with the result of somewhat reducing the swelling of the thyroid. Three or four weeks later slight conjunctivitis was noticed in the lower fold of the left eye, but it disappeared after using a mild boric-acid lotion. There was no protrusion of this eye. The pulse remained about as before, but there was no rise in temperature above normal. Through the early winter the eye remained in excellent condition, and the sight was perfect.

On the 9th of January, 1896, and without previous warning, except the occurrence of slight pain in the temple the night before, the left eye became irritated and the sight affected. I saw the patient the same day and observed well-marked chemosis of the lower conjunctival fold, and protrusion of the eyeball forward and a trifle upward, but the media were still transparent. The ophthalmoscope revealed nothing but extremely tortuous retinal veins. In a day or two very marked optic papillitis set in, the papillæ rising high above the level of the rest of the retina and the retinal vessels becoming even more tortuous than before. The sight rapidly decreased, due not only to this condition of the optic nerve but to haziness and then to absolute necrosis of the cornea. In ten days the appearance of this eye resembled that of its former partner, and sight was reduced to perception of light. Furthermore, persistent pain ensued in the temples and orbit, and soon became unendurable except after using sedatives. Cocain seemed for a day or two to keep the cornea moist, but when that effect ceased cloths soaked in albolene were employed. The lids, it is hardly necessary to say, could no longer be closed over the cornea owing to the extreme protrusion of the globe.

At this time, with a rise in temperature to 103° F., and the pulse more rapid than ever, there seemed to be no recourse except enucleation, though naturally we wished to give the poor sufferer every chance to retain

¹ I notice in consultation with younger men, nowadays, that they talk a great deal about "tension." They say, for instance, "There is tension in that eye." I think, and I always say so at such times, that we ought to cling to the old-fashioned limitations of the word "tension," and say "increased tension," or "diminished tension," for every eyeball, no matter how soft, has some tension or it would collapse *in toto*. To say that an eye has "tension" does not convey an accurate idea of the condition.

some sight. One suggestion was to evacuate any pus that was present in the orbit, but the condition of the tissues in the opposite orbit, still hard and stiff months after enucleation, showed us how hopeless such a procedure would be as it might subject the patient to two operations if no pus was discovered. There was no corneal abscess present, as in the other eye, and as I thought the cornea might perhaps be cleared by some treatment or operation to me then unknown, I consulted all available authorities for similar cases. The only case resembling mine was found in Mooren's "Fuenf Lustren," a book containing innumerable clinical observations, which are often of great value to the ophthalmic surgeon when he is in doubt. The case of Mooren's was that of a woman who for many months had been overwhelmed with mental anxiety arising from the care of a paralytic sister and an aged and feeble father, who was subject to frequent attacks of angina pectoris. The increased action of the heart in this woman was at first attributed to her mental overwork, and the injection of the lower conjunctival fold to a slight conjunctivitis, but after awhile it became plain that the eyeballs were gradually being protruded. Gray infiltration of the cornea soon set in, first in one eye, and then in the other. A week later Mooren was called in, hastily, only to find that during the night the left eye had burst open after violent pain, and on removing the improvised bandages he found the transparent lens lying between the lids, while the vitreous protruded from a large gap in the cornea. The corneal infiltration in the right eye persisted for months, and the slight perception of light gradually increased. After nearly a year of waiting and treatment, an iridectomy was performed, and the patient could see sufficiently to count her own fingers close to her face, but soon again the sight was reduced to mere perception of light. This, then, the only accessible report of a case, did not offer much encouragement for my patient.

While still considering what was best to be done, the corneal infiltration assumed a purulent form, with rapid hypopyon and with the occurrence of a perforating ulcer of the cornea. Finally, a day or two later, the patient insisted that the eye should be removed as he was obliged to confess his utter sightlessness, and he was unwilling to endure such constant pain and suffering. The operation was very difficult, owing to the infiltration of the orbital tissues, and I had to proceed very slowly, the scissors appearing to have no cutting power, though apparently sharp enough in ordinary enucleations. Well-marked purulent choroiditis was discovered on opening the globe. The optic nerve was swollen for some distance behind the globe, the swelling extending into the orbital tissues.

The patient was soon discharged, without any unfavorable symptoms, and is now in even better condition, physically, than when I last saw him one year ago. He still uses the thyroid extract in five-grain doses from time to time for a period of a month or two, and attributes his good health to that form of medication. The thyroid gland is now but little swollen.

A brief résumé of this interesting case shows us, judging from the ophthalmoscopic examination of the left eye

before the cornea became infiltrated, that with the enlargement of the thyroid gland, almost exclusively on the right side of the neck, first the orbital tissues of the right side and then on the left became inflamed and engorged, causing optic neuritis and gradual obstruction of the nutrition of the eyeball. This obstruction occurred first in the optic nerve, then in the anterior portion of the globe, and then extended to the cornea, which desiccated and sloughed. The consequent purulent infiltration of this tissue and occurrence of an ulcer finally excited a typical choroiditis purulenta or panophthalmitis. Finally, the case shows that with proper aseptic precautions, eyeballs affected with panophthalmitis can safely be removed.

SPECIAL ARTICLE.

INSANITY FROM PRISON CONFINEMENT.

By M. V. BALL, M.D.,
OF PHILADELPHIA;

FORMERLY PHYSICIAN TO THE EASTERN PENITENTIARY OF PENNSYLVANIA.

WITH the exception of a few South American prisons, solitary confinement is not in use in any prison in the world. Wherever the so-called cellular imprisonment is in vogue, the convict is not only permitted to see his relations, prison officials, officials of prison societies, etc., but he is allowed to read, to write letters, and to take exercise. In the Eastern Penitentiary of Pennsylvania, of which so much has recently been written and which is now under investigation, solitary confinement has not been practised for the last fifty years at least. And separate confinement has not been possible for the last twenty years (by separate confinement is meant the isolation of the prisoner from his fellow-prisoners). Because of the limited number of cells two and even more prisoners have been obliged to occupy one cell, and only when a convict has been imprisoned for sodomy, or has showed symptoms of insanity, has he been placed in a cell by himself. Under such circumstances it is impossible to say that the system of solitary confinement produces insanity, since that method of correction is practically nowhere in use, but time and time again charges have been brought against the Eastern Penitentiary inspectors to the effect that their system is productive of more insanity than the so-called congregate system. What are the facts?

It is well known that the majority of the convicts that become insane in prisons are persons who have committed serious crimes such as rape, incest, and manslaughter, crimes against the person rather than against property. For such crimes long sentences are usually received. Thus twenty-one insane and imbecile prisoners received into the Eastern Penitentiary during one year (June, 1894, to June, 1895) had an average sentence of three years and eight months, while the average sentence for the convicts generally was not more than two years and five months. Among these twenty-one convicts were several whose term of sentence ranged from five to fourteen years. Another, not included in this list, was serving out a life sentence. While, on an average, twenty-seven per cent. of the general prison population is committed for crimes

against the person, in this instance thirty-six per cent. of the insane persons were sentenced for this reason. It follows, therefore, that if insane convicts are not transferred to regular insane asylums the number in the prisons will constantly increase even if the annual commitment remains the same.

I contend that most of the cases of insanity found in prisons are not the result of confinement but rather the cause of imprisonment; that the insanity is largely responsible for the criminal actions of the particular individuals, and that the judges of the courts have either not recognized the unsound mentality or, recognizing it, have refused to take it into account. One judge, sitting in Philadelphia, gave it as his opinion that because a prisoner was insane "there was all the more reason for hanging him."

The managers of the Eastern Penitentiary have hitherto paid little if any heed to the insane convicts committed to their care. The warden, a man brought up and schooled by Richard Vaux, whose contempt for science and modern ideas was well-known, is inclined to consider a person "inherently depraved" who is not amenable to ordinary reason. In his table of causes of crime, which was compiled by Vaux, we find that of the 22 men spoken of above, the warden has set down the insanity of 3 as due to inherent depravity, 2 to physical disease, 2 to moral weakness, 2 to family influences, 4 to faulty administration of the law, 4 to evil association, and 3 to idleness. For instance, in the case of an Italian who was undoubtedly insane upon admission and who was sentenced for assault and attempt to commit rape, the warden considered his crime as having been due to "too much license and no repressive means to control self-will in the young!" Another man who was sentenced to fourteen years for committing rape, and who had attempted suicide in the county jail, and showed symptoms of acute dementia shortly after his reception, the warden considered "weak in moral power!" A third man, who was insane when admitted and who had committed a murder and received a life sentence as there was doubt as to his mental condition, the warden thinks committed the crime because of "laxity in the administration of the law!"

A man who commits a crime may be sane or insane; if insane he cannot legally be tried for crime; he is not responsible and therefore not culpable. If, unfortunately, his insanity is discovered only after his trial, as very often happens, then he has been tried unjustly and the brand of convict should be removed by law. If he is not a convict, why should he be placed in an asylum for *criminals*?

In my experience in the Eastern Penitentiary it did not happen more than twice or three times during a year that a prisoner who was perfectly sane on entrance (according to our record) and without an insane tendency, became insane during confinement. For these few cases of insanity space can be found in a separate ward in any State asylum. It is a disgrace to the civilization of the present age to imprison the insane, the feeble-minded, and the imbecile as convicts for a definite period, and then after the expiration of their sentence to set them free without let or hindrance, allowing them to commit fresh deeds of

violence and to be again sent to prison for another term of years. I have known of a chronic paranoiac being sentenced to the Eastern Penitentiary six times in the course of eight years for deeds which were clearly the result of his mental infirmity, and my remonstrance against such a procedure was not encouraged by the authorities but rather opposed. I have known of an imbecile boy receiving a sentence of fifteen years for setting a barn on fire, and his knowledge of the right and wrong of his action was no more than that of a two-months-old baby.

The courts are primarily to blame for this state of affairs, but a wise and intelligent prison management should be more anxious to make known this fault and should urge some action to prevent its occurrence. The medical profession is also to blame since because of the confusion that exists in connection with the acceptance of expert testimony the public has been inclined to ignore the findings of alienists and to allow men to go to prison who are fit subjects for asylums. It seems to me that it is necessary for the judges and medical experts to come to some definite understanding in regard to insanity and what constitutes culpability before the insane convict question can be settled.

MEDICAL PROGRESS.

The Results of the Medical Treatment of Perityphlitis.—

KLEINWACHTER has published in *Mitteil. aus d. Grenz. gebieten d. Med. u. Chir.*, Bd. I., p. 717, an interesting article describing the results of treatment without operation of 147 cases of perityphlitis admitted into the medical clinic of Breslau from 1874 to 1889. The object of treatment was to obtain complete relaxation and quiet of the intestinal tract in order to favor the formation of adhesions. The patient was immediately put to bed, and was not allowed to move for any purpose whatsoever. Opium was given, and the diet was strictly regulated. In the beginning of the disease, ice bags were laid upon the abdomen, and later these were followed by warm poultices. Fifteen to twenty drops of tincture of opium were given in the beginning of the illness, and from eight to twenty drops three or four times daily as long as there was pain or distention of the abdomen. No cathartic was given, even if there was no movement of the bowels for from seven to nine days.

A more exact classification of these cases shows that there were 115 of them to which the name perityphlitis would still be given (in Breslau). Of these, 101 patients, or eighty-eight per cent., were discharged cured; twelve, or ten per cent. were improved, while only two, or not quite two per cent., died. In twenty-four per cent. of the cases which could be followed, there was a recurrence, and this occurred almost invariably in less than two years.

This mortality ought really to be given as higher than it is, as the 147 cases include fifteen of peritonitis resulting from perforation of the vermiform appendix, with six deaths. There were also nine cases of perityphlitis, without a death, which gives a mortality for the whole series of about fifty-five per cent.

Hereditary Continuous Shedding of the Finger-Nails.—In the *Journal of Cutaneous and Genito-Urinary Diseases*, June, 1897, MONTGOMERY mentions a case of constant shedding of the finger-nails occurring in a healthy, well-formed Frenchman. The patient's mother and two maternal uncles were likewise affected. Other relatives had bad nails but none were affected in exactly the same way. In his case, some two or more nails were constantly loosening, a process taking three months to become complete, and not accompanied by any pain. The new nails were in every respect normal. An affected nail grew dull and yellowish-white just over the lunula, and then lifted away from the nail-bed from behind forward until it was completely separated.

An Epidemic of Mastitis.—In the *Zeit. f. Geburt. und Gynäkol.*, Bd. xxxvi, p. 473, FREUND describes a moderate epidemic of mastitis which occurred in one of the wards at the Lying-In Hospital in Strasburg. All of the six patients in this ward were affected within seventeen days. The cause of infection at first was not clear. One of the women entered the hospital with an abscess already formed. In another instance, it seemed plain that the abscess of the breast was set up by a nursing infant whose mouth was in bad condition, as it contained aphthous patches and abundant staphylococci. The origin of the other cases was not clearly determined. Direct contact seemed to be disproved, and the writer was of the opinion that the germs were carried from one patient to another by the air.

A New Method of Sterilizing Water.—SCHUMBURG (*Deutsch Med. Woch.*, No. 10, 1897) describes a new method of sterilizing water by the use of bromin, one grain being sufficient to destroy all the bacteria in one quart of water, the bromin afterward being neutralized by ammonia so that a clear and tasteless water is obtained. For this purpose, a twenty-per-cent. solution of bromobromid (bromid, one part; bromin, one part; water, five parts) is used. Thirty minims of this solution are sufficient to sterilize in five minutes one quart of river water. If the water is very hard or very foul the lime salts and the ammonia contained in it neutralize a part of the bromin, and in such cases it is necessary to add the bromin solution until a faint yellow color is obtained and persists for at least half a minute. An equal quantity of a nine-per-cent. solution of ammonia suffices to neutralize the free bromin. It is desirable that these amounts should exactly correspond, although a faint taste either of bromin or of ammonia is not objectionable. When the bromin is exactly neutralized, the water is clear and can scarcely be distinguished from the original water, while the amount of bromin salt which it contains is so small that it has no effect upon the system. This method bids likely to be of especial use in times of epidemic, in war, etc.

The Percentage of Astigmatic Eyes in School Children.—STEIGER (*Corres. Bl. f. Schw. Aerzte*, May 15, 1897) found that of about twenty thousand eyes of children in the primary classes in the schools of Zurich, 1570 were more or less defective. About one-half of these, or 777,

were astigmatic. In some of these the affection was light, but in 662 it was described as considerable, while in 318 it was marked.

Muscular Paradox in Hysteria.—By the term "muscular paradox" ALDRICH (*Cleveland Med. Gaz.*, May, 1897) refers to the apparent inconsistency in the use of certain muscles often shown in hysteria. Thus a man, who while lying in bed can use all of his muscles with quickness and power, may perhaps be unable to use them at all while on his feet. A singular illustration will suffice to show the means used to detect this muscular paradox. Requesting the patient to keep his leg rigidly extended, the examiner grasps the ankles with one hand, while the other is placed in the popliteal space, and the amount of force required to flex is noted. Next, with the hands in the same position as before, but with the leg at an angle of 90° to the thigh, the patient is requested to extend the leg, and the examiner observes the muscular force required to prevent it. Though in these two tests the normal contraction of a single muscle is involved, yet the examiner may find that the resistance necessary to overcome this contraction is in one case perhaps double what it is in the other. Other muscles are to be tested in a similar method.

Actinomycosis of the Face—Recovery.—In *La Presse Medicale* for May, 1897, DUGUET reports a case of actinomycosis which involved extensively the cheek and lower jaw of the right side, in which complete cure was obtained in six months by the administration of large doses of the iodid of potash internally and the application externally, morning and night, of tincture of iodine and glycerin in the proportion of one to four. The patient, in the beginning, took one gram (fifteen grains) of the iodid of potash, which was rapidly increased to five a day without any disturbance of the stomach or the production of any symptom of iodism. Improvement was noticed very early, and gradually the doses of iodid were diminished to two grams (thirty grains) a day. The article is accompanied by colored plates which demonstrate that the cure was complete.

Relief of Thirst in Persistent Vomiting.—In the *British Medical Journal*, April 3, 1897, HARDMAN tells of a case of persistent vomiting in which nutritive enemata had been given for over two weeks. Nothing, either solid or liquid, could be retained on the stomach, and the patient complained bitterly of thirst. For three successive days from forty-five to fifty ounces of sterilized normal salt solution was injected into the cellular tissue of the abdomen and flanks. The patient experienced great relief of thirst, and the general condition was so much improved that an exploratory laparotomy was performed, but this unfortunately revealed a hopeless condition of things. Each saline injection was followed by only a little soreness, and the fluid was completely absorbed in twenty-four hours. From his experience with this case, Hardman is of the opinion that a quart of water might be injected each day into one of the four quadrants of the abdomen, and that by the time the fourth quadrant was used for injection the first would again be available.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, JULY 17, 1897.

THE BILL BEFORE CONGRESS ABOLISHING ANIMAL EXPERIMENTATION IN THE DISTRICT OF COLUMBIA.

THE editorial under this caption which appeared in the MEDICAL NEWS of July 3d has called forth some criticism from Dr. Leffingwell, which is published in another column. In his closing remarks, the doctor affirms that some of the objectionable features of the bill have been entirely eliminated and do not appear as it was reported to the Senate. The doctor regrets that these improvements in the bill, for which he takes to himself some credit, and which, undoubtedly, is justly due him, are "so widely unknown or so frequently overlooked." In this way he very courteously attempts to explain, on behalf of the NEWS, what he claims are misstatements of facts. We beg leave to assure the doctor, however, that the latest revised edition of the bill was before the editor when he penned the editorial in question, and while he recognized the improvement which the bill had undergone, the strictures made upon it are still pertinent, and the opinions there expressed will be the convictions of anyone who will carefully read the revised bill both literally and between the lines.

The alleged misstatements of facts are placed under three heads: The writer denies (1) that the practical effect of the bill would be to prevent all animal experimentation in the District of Columbia; (2) that the Humane Society of Washington is endeavoring to usurp to itself the power of controlling all animal experimentation, and (3) that the cruelties are not imaginary.

If we look into the history of this measure, we find that it originated in the Antivivisection Committee of the Washington Humane Society, and in the various discussions which have followed its presentation it has been particularly asserted that its passage is desired as much for its influence as a *precedent for State legislatures as for its direct effect in the District*. Moreover, in its original draft, inspectors were to be appointed from among the officers of this society. Even now, in its revised form, the bill takes the authoritative supervision of this important scientific work out of the hands of the proper authorities and places it under the direction and control of the political officials of the District. These local officials would necessarily be more or less under the influence of their fellow townsmen and townswomen and reflect in their official acts, the latter's sentiments and desires.

Had there been evidence that instances of cruelty to animals had existed in the District of Columbia, the vigilance committee of this Washington Humane Society would have been able to secure it and present it in answer to the challenge given them for proof of their allegations. In regard to this matter the Secretary of the Department of Agriculture, Mr. James Wilson, in presenting his objections to the bill as it now appears, says:

"It is not shown that there have been any cruel experiments performed in the District of Columbia, or that any such experiments are now in progress, or that there are likely to be any experiments of this character in the near future. The only allegation of such cruelty having been perpetrated was contained in a letter from Dr. A. L. Rauterberg in reference to mutilations of a dumb animal which he had seen in the Army Medical Museum. His statement is indefinite and does not specify the time, the species of animal operated upon, or the person perpetrating the cruel act. The records show that Dr. Rauterberg was at one time employed in the Army Medical Museum in a clerical capacity, and that he has not been connected with that institution for twenty-three years.

Responsible medical officers connected with the museum testify that there have been no painful experiments performed there since 1870, or, so far as they have been informed, previous to that time. Need I say it would not be wise to pass legislation, which may retard science and interrupt investigations now in progress and necessary for the control of disease costing our farmers many millions of dollars annually, upon this inconclusive evidence as to something which is alleged to have occurred in the Army Medical Museum a quarter of a century ago."

As all charges of cruelty have therefore been disproved, it does not seem at all irrational to use the term "imaginary cruelties" in reference to these allegations.

The proposed legislation is unnecessary; the Government laboratories are under proper official supervision, and the laws of the District now in force are amply sufficient to prevent cruelty to animals. This effort to obtain legislation in the District of Columbia by the Congress of the United States is not based upon any evidence relating to abuses in this District, but is being urged by the members of the Washington Humane Society, who have become excited by reading the antivivisection literature sent to them by Dr. Leffingwell and his friends in Massachusetts, who having failed to secure legislation in that State have transferred their field of action to the Capital of the Nation, where they knew in advance that they had a friend in a prominent member of the Committee on the District of Columbia in the United States Senate.

Now, let us consider the main point of the discussion at issue, which is the effect of the bill upon animal experimentation. Upon this point Secretary Wilson aptly remarks, that while there "appears to be a difference of opinion as to the effect which the bill is intended to have, an examination of its several sections shows conclusively that those who favor it need to make themselves familiar with its provisions not less than those who oppose it." In demonstration of this fact, the Secretary proceeds to describe instances in which the bill will restrict, and in many cases actually prohibit very important investigations. For instance:

"We wish to determine whether a calf or a pig will contract tuberculosis by eating infected milk which has passed through the separator, or whether hog-cholera may be contracted from the separated milk from creameries. The only way to determine this is to feed infected milk which has been passed

through the separator. But if an animal contracts one of the diseases in that way it will probably become fatally infected; it will probably suffer pain. As this is not an inoculation experiment, it contravenes the provisions of the bill unless the animals are kept under anesthesia during the entire course of the experiment, which would be absurd and impossible.

"Again, we wish to determine whether susceptible cattle will contract Texas fever when separated from infected ones by an ordinary board fence. It is important to test the question by actual experiment. Here, again, we would contravene the provisions of the bill because if the animals contract the disease they would suffer pain.

"Or, we wish to know whether the contagion of a disease like bovine pleuropneumonia may be contracted from stables, or whether it must always pass direct from animal to animal through the expired air. To determine this, animals must be confined in stables where diseased cattle have been. If they contract the disease they necessarily suffer pain. Hence, the animal must be kept for weeks under ether or chloroform or contravene the provisions of the bill."

These are simply every day cases of experimentation which will be prohibited by this bill. Other important ones are mentioned by the Secretary in the communication referred to, and the assertion is made that many others could be instanced were it deemed necessary. It thus becomes apparent that the provisions of the bill do restrict this class of experimentation and absolutely prevent and prohibit many lines of work. Other provisions of the bill impose heavy penalties whenever an experiment varies in any way from the lines laid down in the bill. Moreover, a system of espionage by inspectors unacquainted with the purpose or necessities for original scientific work in any field, is provided for. These provisions make it possible for a local humane society to be represented in the list of inspectors and enable them to obstruct, harass, and prevent experimentation upon animals by frequent visits of the inspectors, by prolonged investigations of the laboratories, and by repeated calling, through the commissioners, for detailed reports of all experiments. Considering the bill, therefore, in its fairest and broadest interpretation, it must be regarded as a great restriction upon proper scientific animal experimentation, and, when we take into consideration the origin of the bill and the motives which prompted it, *viz.*: "for its influence as a precedent for State legislation as much as for its direct effect in the District," and the persistence of fanatics in

harrassing and obstructing the work of those whom they flatter themselves they are especially called upon to restrain, we are justified in our assertion that the practical and ultimate effect of this bill would be to abolish efficient animal experimentation in the District of Columbia.

ECHOES AND NEWS.

Honors to Dr. Prudden.—The degree of LL.D. has been conferred by Yale University on Dr. T. Mitchell Prudden, Professor of Pathology in Columbia University.

Smallpox in Tennessee.—Since March 18, 1897, there have been reported 22 cases of smallpox in Memphis, Shelby, and Madison counties, Tennessee. The continued prevalence of the disease is causing much uneasiness.

Smallpox at Bellevue.—The Marquand pavilion is under quarantine on account of a case of smallpox which occurred there last month. The patient, a child three years of age, was supposed to be suffering from chicken-pox when admitted to the hospital.

Death of Professor Fresenius.—Professor Carl Remigius Fresenius, the great chemist, died at Wiesbaden, June 10th, of apoplexy. He was born at Frankfort-on-the-Main in 1818. He was made professor of chemistry at the Institute of Wiesbaden, and was the author of several works on chemistry which have a world-wide reputation.

A New X-Ray Apparatus.—A new X-ray apparatus, possessing all the advantages of the Edison machine and none of its defects, has been invented by Dr. Jarvis S. Wight, Jr., and Professor Rufus Sheldon of the Polytechnic Institute, Brooklyn. An improved transmitter, by means of which the ordinary electric-light current can be used, is a distinctive feature of the apparatus.

Yellow Fever at Panama.—Four deaths from yellow fever occurred on a steamer from Panama which arrived on the 1st inst. at San Francisco. Passengers on the steamer say that the authorities at Panama endeavor to suppress the facts in regard to the ravages of the scourge at that port, and that it is dangerous for unacclimated persons to spend any time ashore at the Central American ports.

Sanitarium Struck by Lightning.—The sanitarium of Dr. R. P. Johnson on Missionary Ridge, near Chattanooga, Tenn., was recently struck by lightning and the building destroyed. Although panic-stricken the patients were removed uninjured from the burning building. No lives were lost, but two employees were rendered unconscious by the shock, and Dr. Johnson was slightly injured by a piece of falling timber.

Electric Light and Sailors' Eyesight.—The *Revue du Cercle Militaire* says that men employed on men-of-war are frequently affected with eye complaints which in some cases lead to total blindness. These are supposed to be

due to the intensity of the electric light used on board war ships. It has also been observed that gray and blue eyes, the iris of which is not much pigmented, are more likely to be affected than brown eyes.

Castile Soap and the Plague.—The prevailing impression that the famous soap of Marseilles was made from the pure olive oil of the south of France has been swept away by the fact that the soap factories have been obliged to close because of the quarantine against India. It appears that for twenty years the manufacturers have been supplying the market with an inferior product made from common linseed oil imported from India.

New Puzzle for Scientists.—According to the San Francisco *Examiner* a remarkable instance of an abnormal growth has been discovered in that city by Dr. Yoakum, who recently removed a tumor from the base of the spinal column of a nine-months old boy. The tumor contained a human embryo about four inches long. The bones were nearly all developed, especially the thigh and hip bones and portions of the vertebral column.

A New Style of Letter Linen.—The following letter written on an ordinary gentleman's linen collar was recently received at the San Francisco Board of Health Office: "Board of Health: Having used up all the writing paper I possess in a vain endeavor to have the Bryant Street sewer, from Twenty-sixth to Army, attended to, I am now compelled to use my linen to inform your office that its condition warrants attention. There is evidently some one connected with the Health Office not doing his duty, and whoever the collar fits let him wear it. Within the past year there have been thirty deaths in the immediate vicinity of this sewer, and your records will show that at the present time there are 100 sick children living near this morass. Yours truly, M. P. JONES."

Obituary.—The faculty of Bellevue Hospital Medical College has spread upon its records the following resolutions regarding the death of Dr. J. Lewis Smith. "It is with sorrow that we record in the minutes of the Faculty of the Bellevue Hospital Medical College, the death on June 9, 1897, of Dr. J. Lewis Smith, late Clinical Professor of Diseases of Children. Dr. Smith was a teacher in the College for thirty years. He brought to his instruction a ripe experience and sound judgment, and had attained a most enviable reputation, not only as a public teacher, but as a voluminous writer on the subjects of his special studies. His loss will be deeply felt, not only by the profession, but by the public at large, who benefited so much by his skill and devotion."

The Long Island College Hospital.—This institution will open its next winter's session in the new Polhemus Memorial Clinic, the gift of Mrs. Caroline H. Polhemus of Brooklyn. The building is situated on the corner of Henry and Amity Streets, and has a frontage of sixty-eight and ninety-two feet respectively. The design of the exterior is in French Renaissance. In plan the building is a rectangle with large courts for light and air on the sides opposite the street fronts. The two lower floors

will be devoted to dispensary work. The clinical lecture-room occupies the central section of the building from the third to the fifth floors. The chemical lecture-room on the sixth floor is similar to the clinical lecture-room. The eighth story is given up to the anatomic division, there being two large dissecting-rooms lighted by skylights, a Prosector's room, Demonstrators' room and bone library. The construction of the building throughout is of the most substantial and enduring type and thoroughly fire-proof.

CORRESPONDENCE.

THE BILL RESTRICTING ANIMAL EXPERIMENTATION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Are scientific interests ever really promoted by misstatements of facts? I am sure that THE MEDICAL NEWS does not think so; and that whenever inaccurate statements appear in its editorial columns they are due to misinformation. The NEWS regards with strong disapproval the bill now before Congress, placing the practice of vivisection in the District of Columbia under governmental supervision. But may not this sweeping condemnation rest upon imperfect information regarding the character and scope of this measure? Permit me at least to call attention to your editorial in the issue of July 3rd, and to some grave errors of fact therein contained.

1. You affirm that this is a bill "abolishing animal experimentation in the District of Columbia," and that it is "destined to prevent all animal experimentation." If this were true I confess I should regard such a measure with quite as much disfavor as yourself; but this charge, though again and again repeated, is wholly without basis of fact. I have had some slight influence in suggesting amendments to this proposed law, and I know that whatever restrictions the bill originally contained, it now permits all phases of inoculation experiments, all tests of drugs, of poisons, or of methods of surgical procedure, and in fact all other useful investigations upon living animals, whenever such experiments may be performed while the creatures are anesthetized. (See Sec. 2, clause c.) Is this "abolition of experimentation?" THE NEWS has been misinformed.

2. You state that "the Humane Society of Washington is endeavoring to usurp to itself the power of controlling all animal experimentation" in Government laboratories and elsewhere. Upon what basis of fact does this statement rest? This Humane Society is not once mentioned in the bill, as reported for consideration; the President of the United States appoints the inspectors, and Government officers only have anything to do with experiments or experimenters. To suggest that above these officials, is the usurping power of the Washington Humane Society, is to confer a potency of influence where none exists.

3. I am heartily sorry to learn in the same editorial that the advocates of this bill are in favor of preventing the occurrence of "imaginary cruelties," for if abuses of

vivisection are unknown, all effort toward prevention is wasted force. But is it all imagination? In his address before the American Academy of Medicine last year, the late editor of THE MEDICAL NEWS—Dr. George M. Gould—said: "At present the greatest harm is done to true science by men who conduct experiments without preliminary knowledge to choose, without judgment to carry out, without true scientific training or method, and only in the interest of vanity. . . . I have adduced this single American experiment, but I purposely refrain from even mentioning the horrors of European laboratories. . . . Dr. Klein, a physiologist before the Royal Commission testified that he had 'no regard at all' for the sufferings of the animals he used. . . . It may be denied, but I am certain a few American experimenters feel the same way, and act in accordance with their feelings." Does Dr. Gould here refer to "imaginary" evils? I adduce his name only as a witness, not as an advocate, for if I mistake not, he is as strongly opposed to the bill as yourself. But no writer has more forcibly presented the evils to remedy which this bill was designed. I do not believe that, if it becomes a law, it will in the slightest degree impede any form or phase of useful investigation. In the first draft there were some features which have been entirely eliminated from the present measure, and it is to be regretted that this fact is so widely unknown, or so frequently overlooked.

ALBERT LEFFINGWELL, M.D.

BROOKLYN, JULY 7, 1897.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

"THE ÆSCULAPIAN ASSISTANCE AND INTERMENT COMPANY, LIMITED"—THE THOMAS HOGE MEMORIAL WARD OF THE PRESBYTERIAN HOSPITAL—FRESH-AIR PIERS FOR THE MASSES—DR. S. WIER MITCHELL'S RUMORED DEATH—FOURTH OF JULY CASUALTIES—VITAL STATISTICS.

PHILADELPHIA, July 10th, 1897.

THERE is a certain class of people in every community who, when they fall ill, or imagine themselves ill, repair to their favorite dispensary or hospital, and accept as a matter of course the free treatment given them; all sorts and conditions of men are included in this class, from the coal-heaver to the prosperous-looking individual whose personal appearance infers a lack of familiarity with the seamy side of life; but they are all alike in one thing—they pride themselves in getting something for nothing, and they get it unconditionally, and without embarrassing questions about their deservedness, thanks, very often, to the "charity" of some pseudo-philanthropist who has thought it beautiful and Christianlike to found a free dispensary for his fellow-men. Then there is another class of people whose motives are precisely the same as the former's, but who lack the assurance of the dispensary habitué, for they are conscious that they are not those for whom free dispensaries were intended, and they are afraid to pretend that they are; these people also are of a single mind about one thing—they pride themselves in getting something for as near nothing as possible, and they pro-

ceed to get it by patronizing twenty-five cent "specifics," or by taking the drug-store clerk's advice when they are ill, or by ingenuously asking their doctor friends leading questions about their maladies, hoping to elicit some counsel gratis.

For the latter class there exists a veritable god-send in the garb of a certain medico-commercial concern which may be termed "The Æsculapian Assistance and Interment Company, Limited." This enterprising corporation from all appearances finds a profitable field of labor in this city, if elaborate office suites in a prominent business section of the town, and large numbers of visitors to these offices are indications of prosperity. It agrees to furnish the sick or injured seeker for medical bargains, for the sum of twenty cents weekly, with the "best and promptest medical treatment in the city," or, should the patron not survive this excellent and prompt medical treatment, and pass to a world as yet uninvaded commercially by the company's agents, he or she is guaranteed the following gorgeous funeral arrangements, the contemplation of which, from the standpoint of this class of the community, must surely take away the sting of death: "Undertaker's services, including laying out, and advertising funeral notice in at least three daily papers, also one black-trimmed casket for an adult, or a white-covered coffin (if under thirteen years of age), the said casket or coffin to be satin-lined, with pillow to match, and to have from four to six nickel-plated handles, and a nickel-plate with name and date of death inscribed thereon; one plain box for casket, also one shroud of good cashmere, ice for preserving the body (not longer than four days), provisions for draping the room (candles, if wanted), the gloves and crape at the door, also furnish a grave, including and filling the same, in any cemetery in or about the city or town herein mentioned; also, a hearse, with five carriages, white marble tombstone if the party be over thirteen years of age when death occurs; a hearse with four horses, white marble tombstone, if the person is between six and thirteen years of age, and a hearse and three carriages and white marble tombstone if the person is between two and six years of age." In such a strain the prospectus of the company continues for several pages, at times lapsing into such enthusiasm that construction of sentences is sacrificed for vivid word pictures.

With such a *fin de siècle* institution within the reach of the "get-it-as-cheap-as-you-can" class, the question arises what will become of the quarter-dollar "specific" seller and the drug-store "doctor" who must decline to furnish tombstones and satin-lined caskets with their services? But the doctor friend escapes the innocent questions which he isn't supposed too see through, but which he does. All of which tends to add to one's belief in a certain ancient saw relating to the zephyrs of an evilly inclined wind.

Through the liberality of Mrs. Elizabeth Pleasanton, the Presbyterian Hospital will soon possess a handsome structure for the exclusive treatment of diseases of the nervous system. It will be known as the Thomas Hoge Memorial Ward, in memory of a relative of the donor. The new building will be four stories in height, and is to

occupy a prominent place in the hospital grounds adjoining the Administration Building. The first floor will contain thirteen apartments, one of which will be devoted to skiagraphy, and another to ophthalmologic work; the second floor is to be used for ward purposes, diet kitchens, electrical and hydrotherapeutic rooms; "rest" rooms and apartment for the surgeons occupy the third floor; while two operating-rooms, with adjoining apartments for sterilizers and surgical dressings, will be situated on the top floor.

It is expected that the new ward will be open for the reception of patients by next October. Dr. S. Wier Mitchell and a corps of assistants will have charge of the work of this new department of the hospital.

The establishment of "Fresh-Air Piers" along the river front is doing valuable service in improving the condition of the poor of the lower classes, and offering them an opportunity to escape for a time the reeking atmosphere of the alleys and courts, and the intolerable heat of the tenements. The woman of the tenement may bring her sick baby to one of these piers each night, and remain until the following morning; young and old alike are welcome to use these breathing spaces, and such adjuncts to comfort as easy seats, well-arranged lights, and covering overhead are provided. The piers, which are similar to those along the New York water front, are under the care of the Health Protective League, of which Dr. Rachael D. Skidelsky is the president; they are open every week day from 7 P.M. to 7 A.M., and all day Sunday. It is hoped that the establishment of such breathing spots for the masses will result in the alleviation of much suffering, and in a reduction of the high infant mortality among this class of the population.

A rumor reached this city the early part of the week alleging the death in London of Dr. S. Wier Mitchell. Fortunately, upon careful inquiry, the report could be stamped as a senseless canard, due most likely to some news-ridden journalist's elastic imagination.

As a result of the celebration of the Fourth of July, the various hospitals of this city treated 120 accident cases attributable to the use of fireworks, one of which proved fatal. "Heat" cases numbered twenty-one, the majority of which occurred among the celebrants, so that it may be said that the cost of this patriotic remembrance of our country's decision to strike out for herself resulted in a total of 141 casualties.

There were thirty deaths from diphtheria, and fifteen from scarlet fever last month at the municipal hospitals; 116 cases of the former disease having been admitted, and 145 of the latter.

Post-graduate Facilities in Russia.—There are facilities for post-graduate study at the ten Russian Universities and at the Army Medical Academy at St. Petersburg. Courses on various special subjects, varying from one to three months, are held, and the fee charged is a small one, averaging about \$2.50. There are abundant opportunities for graduates desiring to do original scientific work in the laboratories of the universities and hospitals.

OUR VIENNA LETTER.

[From our Special Correspondent.]

PASTOR KNEIPP'S METHODS, PATHOLOGY, AND THERAPEUTICS, AND THE LESSONS SUGGESTED BY HIS SUCCESS—PROFESSOR PALTAUF AND THE INEFFECTUOUSNESS OF PLAGUE SERUM—LUMBAR PUNCTURE IN THE DIAGNOSIS OF MENINGITIS AND ALLIED CONDITIONS IN CHILDREN.

VIENNA, June 25, 1897.

THE Vienna papers recently have contained daily bulletins on the condition of Pastor Kneipp's health, and the announcement of his death, which has just occurred, occasioned deep regret. There is scarcely a medical man in Europe in whose condition so much general interest would have been displayed. It was in a medical way that Kneipp gained celebrity, yet modern medicine owes him very little, if anything at all. Some time when another Oliver Wendell Holmes writes on the vagaries of therapeutics in our nineteenth century, Pastor Kneipp and his "water cure" will occupy as prominent and as inexplicable a place as the "unguentum armamentarium" of Sir Kenelm Digby, or Bishop Berkley's tar water in other times. More people have gone to Wörlshofen during the last ten years to consult the simple, well-meaning country clergyman about their health than would suffice to keep at least half a hundred doctors busy all the time. Some years ago 20,000 was set down as a conservative estimate of the number of annual medical pilgrims to this modern shrine. In the course of time the number has increased, not diminished. People came from all parts of the world. Australians, Americans, East Indians, as well as Europeans, have come to Vienna every now and then to consult some distinguished regular physician before going to Wörlshofen for Pastor Kneipp's "cure." These are the ones who somehow have felt the absurdity of what they were doing, and yet, spurred on by hope and the example of others have continued their journey after satisfying the last qualms of common sense by a final medical consultation.

The little town of Wörlshofen has more than doubled in size, and, without any special natural advantages, has become one of the most popular health resorts in Europe. People of all classes have flocked to it, and members of reigning royal families have been glad to become Pastor Kneipp's patients. The Empress of Austria obediently took her daily sprinklings and baths and her daily walk barefoot in the grass at his direction. He was summoned some time ago to prescribe for the Pope, and a distinguished member of the Rothschild family went to Wörlshofen in his private car to consult him, and used it as a hotel during his stay, because the inns were not good enough for him. He, too, had to go barefoot in the dewy grass in the early morning; but this is not even considered an eccentricity in Wörlshofen, as half the world there has been doing it uncomplainingly for years. And the secret of it all is the wonderful influence of mind over body, and the fact that change of scene and mode of life will cure half the chronic ills that flesh is heir to. Pastor Kneipp's book, "My Water Cure," of which some sixty editions have been exhausted in less than ten years, besides a num-

ber of editions in most European languages, gives all the details of his system. Its pathology is of the simplest, crudest kind, a bit of the old humoral theory serving to explain the etiology of practically every ill. All disease is due to impure blood and corrupt tissue humors. All disease, even organic heart and nervous lesions, disappear when the blood and humors have been properly cleansed. Blood purification was the motto of the empirics before Hippocrates' time. It has always been the slogan of the charlatan, and it is the supposed secret of the success of the harmless, wonder-working sarsaparillas and a hundred other panaceas of our own day. Not that Pastor Kneipp is to be classed with the crowd of humbugs who are in the medicine business for revenue only, and who everywhere are allowed to continue the humbugging of a readily deluded public. He was without doubt a sincere believer in himself and his theories, however absurd they may seem. Nothing is clearer proof that psychical conditions are contagious quite as much as physical affections than to see how ideas utterly unreasonable may be generally accepted when urged with straightforward simplicity and the ardor of conviction.

And so a book which has for its groundwork the popular fallacies of times long past and the simple remedies of the grandmothers of generations ago, instead of being considered as the idle fancy of a self-sufficient, but ignorant, country clergyman, has been taken seriously in our day of vaunted popular education. The exposé of his system by himself serves as a great advertisement. His cases included the cure of cancer, when taken in time, by cold douches and baths, and of organic heart disease, children's paralysis, and epilepsy by the same means. Pneumonia he *cured* in three to five or, at most, seven to nine days by the application of a poultice of coagulated milk. He was certainly not the first to cure pneumonia by simple means in such a short time, but when the coagulated milk poultice is said to *cure* pleurisy, peritonitis, and pelvic inflammation, then there is cause for wonder. Old popular ideas in medicine are played on with great effect, and hygienic formulas that were supposed to have a meaning years ago are once more put forward for the solution of intricate medical questions.

A tendency to relapse of any affection was overcome by "hardening the system," whatever that may mean, the method employed being that of cold baths, douches, and walking barefoot in wet grass, preferably in the early morning. The old doctrine of the striking in of secretions and eruptions, and the consequent danger to the system, was insisted on, and the increase of "transpiration," a mysterious process which is brought about by the plentiful use of cold water externally, which removes "noxious humors" from the blood, and so cures all ordinary human ills, was the main indication of his therapeutics. Beyond cold water, the infusion of hay flowers, also for internal use, was highly recommended.

There would seem to be a lesson or two in these days of nihilistic therapeutics and over-specialized medicine in Pastor Kneipp's wonderful popular success, for his name has become a household word all over Europe without any of the advertising methods that betoken the mere

charlatan. One cannot help thinking that perhaps, too much attention is being paid by the practising physician to the more scientific branches of his profession, to the neglect of therapeutics, because the latter is empirical and unsettled, it being forgotten that, after all, the application of therapeutics constitutes his only real *raison d'être*. On the other hand, an overestimated specialism devotes itself too much to the organs it is particularly interested in, and forgets that it is often improvement in the general health which will best restore these organs to their proper functions. A hundred years ago, homeopathy owed its successful introduction to an analogous error in another direction. Will the lesson of the success of the irregulars be lost in this generation?

At the recent meeting of the Imperial Vienna Medical Society, at which the report of the Austro-Indian Pest Commission was discussed, Professor Paltauf mentioned some attempts which had been made to immunize dogs with pest serum. Though carefully done, the animals invariably died of marasmus. As a result of his experiments, Paltauf agrees with the unfavorable observations of the Commission on Yersin's serum. He is inclined to think that the serum-therapy of the disease is extremely improbable.

A series of eighty cases of meningitis, in which lumbar puncture was done for diagnostic purposes, has just been reported (*Wiener klinische Wochenschrift*) from Professor Widerhofer's clinic. In sixty-two of the cases there was question of tuberculous meningitis. In nearly all of the cases the bacilli, though sometimes in small numbers, could be demonstrated. When the symptom complex of tuberculous meningitis was present, and microscopic analysis of the cerebrospinal fluid negative, its cloudiness and the increased pressure were of diagnostic importance. The limits of the normal physiologic pressure of the cerebrospinal fluid are, unfortunately, too little known to allow of the formulation of rules which can be followed with assurance. Inoculation experiments, when bacilli were not found in suspicious cases, almost invariably confirmed the clinical conclusions.

As to the important matter of the differentiation of other forms of meningitis, so important as regards duration and the absolute prognosis, lumbar puncture was especially useful. The streptococcus and the Weichselbaum-Fränkel diplococcus could always be found in their specific meningitides, while hemorrhagic fluid seemed pathognomonic of epidemic cerebrospinal meningitis. The value of the procedure, too, in differentiating conditions which simulate meningitis from the basal pressure symptoms they produce, as tumors, etc., was worthy of special note. In seven cases it absolutely established the diagnosis of the absence of meningitis. In but one or two of the cases did the puncture produce any serious symptoms. It was always done without an anesthetic, the condition of hebetude usually present being enough to guarantee against sudden movements on the part of the patient that might have proved seriously inconvenient. In children, the point of puncture recommended is between the second and third lumbar vertebrae, not between the first and second, as in adults, in whom the cord is longer.

TRANSACTIONS OF FOREIGN SOCIETIES.

London.

TWO CASES OF "DERMATITIS MALIGNA"—NON-PERFORATING RUPTURE OF THE HEART—THE COMMONER FORMS OF HEADACHE AND THEIR RELATION TO ARTERIAL TENSION—CHRONIC HYDROCEPHALUS—THE AMOUNT OF ANASTOMOSIS IN THE MESENTERIC VESSELS—THE RECOGNITION DURING LIFE OF ADHERENT PERICARDITIS—MYOMA OF THE VERMIFORM APPENDIX—A WHOLE PENCIL OF NITRATE OF SILVER SWALLOWED, AND RECOVERED FROM.

AT the session of the Pathological Society, held May 4th, ROLLESTON and HUNT showed *two cases of "dermatitis maligna,"* in both of which carcinoma subsequently developed. One was that of a man aged sixty, in whom a characteristic raw, glazed, vividly red condition of the skin had existed above the pubes for eight years. Two years ago three nodules of carcinoma developed. Removal of the whole growth has not been followed by recurrence. The sweat glands were dilated, but did not appear to be undergoing any carcinomatous change. The carcinoma was a spheroidal-celled one arising, in the opinion of the reporters, from the sebaceous glands.

The second case was in a woman forty-five years old. In this instance the skin affection began in the sinus of a mammary abscess, eight years previously. It spread widely, and a year ago a cancerous nodule was observed. At operation the whole affected area, together with the glands of the axilla, were removed. There has been no recurrence. This carcinoma was a squamous celled one, showing a transition to the spheroidal-celled type. Neither the mammary gland nor its ducts was in any way involved, and it ought, therefore, not to be called Paget's disease, that name properly being reserved for a long-standing dermatitis of the nipple, as originally described by Paget.

THIN saw in the first of these two cases one of the more ordinary forms of epithelioma; the small cell infiltration of the papillary layer was well-marked, and in this respect differed from the ordinary forms of epithelioma. Hence, the value of the term "papillary malignant dermatitis." He doubted if the sebaceous glands were ever the source of carcinoma, including in this statement "rodent ulcer."

SPENCER thought the term "malignant dermatitis" ambiguous and obscure, for the dermatitis is only antecedent to the malignancy, and the word malignant does not of necessity convey the meaning of a new growth, but may refer to the inflammatory process itself.

FOX exhibited an instance of a non-perforating rupture of the heart, occurring in a stout woman of good health and active habits, who was seized with precordial pain after a cold bath. Morphine, hypodermatically, and a small venesection, gave some relief. Death followed after forty-eight hours. The pericardium was found to be full of blood. The heart was very fat, and there were two small rents in the walls of the left ventricle which did not perforate. It appeared that the distension of the fatty

heart had ruptured the exocardium at these points, causing a slow leakage of blood, which produced death in two days.

At the session of the Hunterian Society, held April 28th, FOX described *some of the commoner forms of headache, with especial relation to arterial tension*. The determination of the tension present rests partly on the sustained character of the pulse, and partly on the accentuation of the second sound of the heart, as heard over the aorta and in the neck. The typical headache due to anemia is frontal and throbbing, similar to that caused by constipation. In albuminuria the pain is usually in the top of the head, and is not relieved by lying down. These forms of headache are all attended by increased tension, and this is true of the majority of cases of migraine. Besides the all-important constitutional treatment, cannabis indica is the most useful remedy in these cases, and may be pushed to intoxication without fear. The fresh extract is the most reliable form of this drug. For headaches, associated with low tension, including those due to tachycardia, alcohol, cough, and amenorrhea, caffeine is the remedy *par excellent*. In middle life, heart disorders cause headaches, with increased tension, perhaps, in the earlier stages, but diminished tension in the later ones. In the old, the steady increase in blood pressure, the senile heart and the asthenic dilated heart, bring their own head discomforts. In the *plus* tension of old age, the saline aperients are often of great value.

Before the Clinical Society, at the meeting held May 14th, TAYLOR read a paper on *chronic hydrocephalus*, and reported a case which ended fatally at the age of sixteen years. The patient had in infancy a large head, but grew up strong and well, attended school, and learned to play the violin. Later he learned typesetting, at which he was employed until he was taken with his last illness. This began with headache and vomiting, followed by dizziness. In the hospital his head was found to measure twenty-three inches in circumference. A few days later the head was retracted and paralysis set in, extending from the feet upward. He died with paralysis of the diaphragm seventeen days after the sickness began.

The autopsy showed the bones of the skull to be much thinned and the ventricles to contain about thirty ounces of fluid. The retention of the mental powers in this case until such a late period of life is very unusual.

LOCKWOOD related a case which throws light on the *amount of anastomosis in the mesenteric vessels*. A man aged sixty-four attempted suicide by stabbing, using a carving knife. The wounds inflicted were all in the mesentery. One of them was parallel to the bowel, and only half an inch removed from it, and had divided an artery of considerable size. The several mesenteric wounds were sewed up, including the one described, as it was only three-quarters of an inch long, and it was not thought that it would deprive the bowel of any considerable supply of blood. The bowel itself was not injured. The man died after two days, and it was found that the intestine opposite the rent referred to was almost gangrenous. A careful examination of other mesenteries re-

vealed the fact that there are no loops of anastomosis within half an inch of the bowel, and that therefore, in the case in hand, the bowel should have been resected.

MARSH mentioned the case of a man thrown from his horse while hunting, and striking upon a heap of stones. There were no immediate symptoms, and he went to his business on the following day. He then rather suddenly collapsed and died. The intestine was gangrenous for several feet, owing to a rent in the mesentery which had severed a large branch of the superior mesenteric artery without, however, giving rise to any great hemorrhage.

TAYLOR called attention to the fatal cases reported as being due to thrombosis of a branch of the mesenteric artery, producing death of the gut. Such cases show that the anastomosis of the mesenteric vessels is not to be relied upon.

At the meeting of the Leeds and West-Riding Medico-Chirurgical Society, held April 9th, CHURTON showed a *heart with an adherent pericardium, the diagnosis of this condition having been made during life*. Old adhesions existed between the lower part of the left ventricle and the pericardium, and in consequence the eleventh rib was distinctly drawn in at each systole. This sign, which is known by the name of Broadbent, was observed a few days before death. How long it had existed there was no means of determining.

CHURTON also showed a *myoma of the vermiform appendix*, simulating recurrent appendicitis. It was a sessile tumor, the size of a small bean, and situated about three-quarters of an inch from the distal end of the appendix, occluding the lumen at this point. Its presence was not detected until the appendix had been removed and cut open. There were no peritonitic adhesions or other evidence of inflammatory action.

DRURY described *his own experience with a large dose of nitrate of silver*. A year ago, after a week's illness, it was decided to make an application of nitrate of silver to his throat. In the attempt to do this the whole pencil (twenty-five grains) slipped down the esophagus. His feelings were indescribable. There was intense gastric pain, and a sensation as of impending death. From the mouth and nose a froth welled up, due, no doubt, to the decomposition of the silver salt and liberation of hydrogen by the hydrochloric acid in the stomach. There was an irresistible feeling that the pencil was still lying in the esophagus. This was so horrible to contemplate that he insisted, against all advice, on the passage of a probang, which failed to bring out anything. Mustard was given in large quantities and free vomiting induced. No trace of the salt was to be seen in the vomited matter. Collapse and great exhaustion followed, and he was kept for some days on a milk diet. There was no further vomiting, but constipation. The temperature for some days was subnormal, but all these symptoms gradually disappeared. During the fortnight following the accident there was complete desquamation of the whole skin, and during the subsequent year there was more or less dyspepsia, but there had been a certain amount of this trouble before the accident.

Berlin.

SARCOMA OF THE LIVER AND KIDNEY WITH TUBERCULOSIS OF THE LUNG—TUMOR OF THE BRAIN WITH UNUSUAL LACK OF SYMPTOMS—THE CARE OF INFANTS IN HOSPITALS AND ASYLUMS.

At the session of the Medical Society, held May 5th, BAGINSKY presented the organs of a child aged eighteen months, in whom the right side of the abdomen was markedly distended, especially well up toward the hypochondrium. Here could be felt a soft, well-nigh fluctuating mass occupying especially the region of the liver, extending downward to the umbilical line, and backward into the lumbar region. Nowhere in these areas was there any tympanitic resonance. The urine was almost normal, containing no renal elements but a trace of albumin. The child had a fever, and as it was considered probable that there was a large abscess present a needle was thrust into the swelling, but only a few degenerated cells were obtained. An exploratory incision was then made, which revealed a dark-brown, soft mass—probably a tumor growing from both the liver and the kidney. This supposition was confirmed at the autopsy which followed the operation by a short interval. The kidney itself was almost intact but completely surrounded by the tumor, which apparently sprung from its hilus. The growth had pushed forward under the liver, involving this organ, while in the lung and bronchial glands were masses which were at first regarded as metastases, but which the microscopic examination showed to be typical of tuberculosis. The tumor was a spindle-celled sarcoma. A combination of sarcoma and tuberculosis has been reported before, though it is by no means a common occurrence.

A second case of sarcoma was reported by BAGINSKY, this tumor being found in a child 6½ years of age. At autopsy it was found that a myxo-angio-sarcoma of great size had surrounded the corpus striatum and optic thalamus of the right side, extending into the lateral ventricle and reaching also to the left side, where it at least pressed on the corpus striatum. The remarkable fact in the case was that in spite of the situation of the tumor and its great size, none of the symptoms were present which are ascribed to tumors situated in the corpus striatum and extending to the optic thalamus. The symptoms were only those of a large brain tumor, and especially there was no paralysis, which is said to be present in tumors of the corpus striatum.

HUEBNER thought that the absence of paralysis was due to the fact that the tumor chiefly affected the gyrus fornicatus, which does not belong to the motor portions of the brain.

A paper upon infants and infant hospitals was read by HUEBNER. The writer expressed his regret that the infant mortality remained so high, and gave rules for cleanliness to be observed in the artificial feeding of infants. The various food mixtures were also spoken of. The treatment of these young infants in hospitals ought to be carried out in accordance with the following rules:

1. On account of the great difficulties which are connected with bottle-feeding, every mother physically capa-

ble of nursing her child should be obliged to do so. That this can be done at no great expense is seen in the "Kaiserliche Kinderheim" in Gräbschen, near Breslau.

2. Bottle-fed children should be separated from the others, and not more than four should be placed in one room. Very sick children should be treated in single rooms.

3. The percentage of nurses to patients needs to be considerably greater than in adult hospitals. Three day nurses (two for feeding and one for the care of the "lower half" of the children), with two night nurses, that is five in all, may be regarded as the maximum number for eight infants.

4. An infant's hospital should be kept as such, and should not be allowed to serve as well the purposes of an orphan asylum. The length of time which it is necessary for a baby to remain in the hospital can only be determined in each individual case.

5. The expense of such an institution will naturally be high, but in the light of our present experience there will be a mortality far below that obtainable in the old institutions where careless methods have usually prevailed.

NEUMANN thought that the great expense of caring for children in the thorough manner described would be in part avoided by the provision of sufficient asylums to receive the children which are no longer in need of hospital care. In Berlin, at least, such institutions are lacking, and, as a result, the children have to be kept in child and adult hospitals.

SOCIETY PROCEEDINGS.

NATIONAL CONFEDERATION OF MEDICAL EXAMINING BOARDS.

Seventh Annual Meeting, Held at Philadelphia, May 31, 1897.

The Chairman, DR. W. W. POTTER of Buffalo, read his annual address, taking as his subject

RECIPROCITY IN MEDICAL LICENSURE; A PLEA FOR INTERSTATE INDORSEMENT.

In this he expressed himself as thinking that the remedy for the prevailing evils lies in legislative enactments secured by the demands of an enlightened public opinion. Twenty-seven States, he said, now require separate examinations, and fifteen of them demand diplomas from recognized colleges when the candidate presents himself before the board. The value of the same law in all the States was dwelt upon and a review made of the different laws in the different States. During the past academic year he reported the establishment of new examining boards in the District of Columbia, Indiana, Idaho, and New Hampshire, showing that advancement was being made in State control. In closing, he stated that the confederation favored reciprocity in securing proper general laws in all the States.

A resolution authorizing the appointment of committees to make thorough investigation of the different medical schools throughout the country, so as to distinguish the good from the bad, was referred to the Executive Com-

mittee to report on at the next meeting. The question providing ways and means of securing reciprocity among the States, was referred to the Executive Council.

The report of a special committee appointed at the previous meeting was then heard. The committee concluded by making the following recommendations:

"That, as far as may be vested in the discretion of existing examining and licensing boards, the rule be enforced that any college, to be in good standing, must enforce entrance requirements, embracing the studies of grammar, geography, two years of Latin, arithmetic, algebra (through quadratics), plain or solid geometry, physics, rhetoric, United States history, and one modern language other than English, or a high-school diploma issued after four-years' attendance, and based upon examination in the foregoing subjects."

It also recommended that the Medical College Association amend its constitution by advancing the requirements for admission, so as to include all of the above subjects.

DR. EUGENE BEACH of New York presented a resolution providing that when, for any reason, a license to practice medicine in any State has been revoked or suspended, the proper officers of boards of examiners in other States should be notified of the facts. It was adopted unanimously.

Dr. Potter was re-elected President, and Dr. A. Walter Suiter of Herkimer, N. Y., was re-elected Secretary and Treasurer. The new Vice-Presidents are Drs. L. B. Godfrey of New Jersey and William Bailey of Kentucky.

THE AMERICAN ACADEMY OF MEDICINE.

The regular annual meeting of this important body was held in Philadelphia on May 31, 1897. During the morning session, much of which was devoted to executive business, the following officers were elected and the names of many new members were added to the roll: President, Dr. L. Duncan Bulkley of New York; Vice-Presidents, Dr. John B. Roberts, Philadelphia, Dr. V. Y. Bowditch, Boston, Dr. Charles Dennison, Denver, Dr. F. T. Rogers, Providence; Secretary and Treasurer, Charles McIntire, Easton, Pa.; Assistant Secretary, Walter L. Pyle, Philadelphia.

DR. J. W. GROSVENOR of Buffalo presented an exhaustive paper upon

THE RELATION OF ALCOHOL TO PREVENTIVE MEDICINE.

In this he dwelt upon the influence of alcohol and drunkenness in the production of idiots, lunatics, epileptics and criminals, and by statistics was able to trace a very large percentage of accidents, including suicides, to the same cause. He concluded that if a board of health for the safety of the community can rightly kill the butchers' diseased cattle, on what ground can it be forbidden to destroy the saloon-keepers' poison liquor? It may be objected that such an act would be an infringement of personal liberty, but it is not so. All right methods should be used for elevating to a higher plane man's physical, mental, and moral nature, and to accomplish this noble object due recognition should be given to the part played by alcohol as an antagonist of preventive medicine.

Other papers were presented, with more or less discussion, upon

THE TRUTH ABOUT CALOMEL—THE GREAT PHYSICIAN OF THE REVOLUTION—WHERE SHALL WE PUT UP THE BARS—A PLEA FOR PRELIMINARY EDUCATION—MEDICAL EDUCATION.

A special discussion of

THE RELATION OF THE COLLEGE TO THE MEDICAL SCHOOL

had been arranged and views of three gentlemen who were solicited to speak upon this topic proved exceedingly interesting. DR. BAYARD HOLMES of Chicago spoke as Secretary of the Association of American Colleges; ATHELBERT D. WARFIELD, L.L.D., as President of Lafayette College, and DR. WILLIAM PEPPER as ex-Provost of the University of Pennsylvania,

Dr. Holmes presented certain demands which were made in behalf of the Medical School. Among these demands was one that due credit should be given the Medical School's courses; another, that it should not be made a "hired man" for the service of the University. In certain State schools he knew of, the speaker said, the medical school earns money for the other departments of the University, maintaining expensive chairs there. He complained, too, that the professors of literary institutes assume a lofty superiority toward medical colleges and frequently strive to dissuade young men from attending medical lectures. Another complaint was that students frequently are not given credit in their bachelor's degree for allied or special work done in some medical subject.

Dr. Warfield contended that mental discipline and culture, to be obtained at college, should be prerequisites for a medical man, and he was of the belief that medical schools which desire the attendance of college-bred men must raise the standard of admission. Colleges can relieve the medical schools of some of the elementary work in chemistry, biology, etc., and this preliminary instruction is better given by a teacher who devotes his entire time to the one branch, as in a college, than to the busy practitioner who snatches a few hours from his practice to lecture to large classes in the medical school. A new difficulty in a general education, he thought, was the "short-cut" method of special courses.

Dr. Pepper deplored the ruinous loss of time, and the consequent insufficient mental training, due to the turning from one curriculum to another, and declared that, above everything else, co-ordination of studies, from the kindergarten to the professional school, were absolutely necessary. However, the co-ordination which will make this possible will never come to pass until teachers meet, and, expressing confidence in each other's work, strive to attain the best end.

DR. J. MCFADDEN GASTON of Atlanta thought a year or so spent under the guidance of a preceptor before entering upon the final study for admission to the profession had great advantages.

DR. A. M. TALLEY of Columbus, S. C., regarded the requirement from students of a preliminary classical education important in maintaining the name of medicine among the learned professions.

DR. HENRY M. HURD of Baltimore was of the opinion that it was impossible for the student in many instances to select his profession early enough to shape his preliminary course toward the desired end.

GERMAN SURGICAL SOCIETY.

Meeting Held at Langenbeck Haus, Berlin, April 21 to 24, 1897.

[From our Special Correspondent.]

(Continued from page 31.)

THIRD DAY—APRIL 23D.

The President, PROFESSOR BRUNS of Tübingen, in the Chair.

The proceedings were opened by the reading of a paper, entitled

THE OPERATIVE TREATMENT OF HYPERTROPHY OF THE PROSTATE,

by PROFESSOR HELFERICH of Greifswald. He sketched the history of the operation of castration for this condition, and quoted a number of statistics relating to its successful employment. Personally, his experience had been that resection of the vas deferens is equally effective in the majority of cases in which operation is indicated. The prostate should always be examined carefully both before and after operative measures have been instituted, rectally and by means of the cystoscope. He had noticed that, although micturition or catheterization is more easily accomplished after such an operation has been performed, psychic disturbances, often of a marked character, are present in most cases.

The speaker referred in favorable terms to the use of Bottini's galvanocautery in cases of prostatic enlargement, and said that the very slight constitutional derangement following its employment was a point largely in its favor. Regarding the ligation of the internal iliac artery, he said that several remarkable cures had been reported, and that this method of procedure was to be recommended in severe cases. Suprapubic cystotomy may be indicated under certain conditions, but is merely a palliative measure.

During the discussion which followed, DR. MIKULICZ reported 50 castrations, in which 29 resulted in a reduction in size of the prostate, 9 in death, 1 in acute mania, and in the balance, no improvement. Of 45 cases of resection of the vas deferens, 10 resulted in a diminution in size of the gland, 27 in improvement of symptoms, and in 8, no improvement. Of the latter, 3 patients were unimproved after a subsequent castration.

DR. BIER of Kiel said that good results have been obtained from ligation of the internal iliac artery for this condition, but on account of the difficulty of the operation it is not to be recommended, except in selected cases. He had lost one patient from septic peritonitis, upon whom he had operated in this way, and two from pneumonia.

DR. MÜLLER of Aachen then showed a patient who had had a defect of the tibia covered by an osteoplastic flap from the fibula. The flap had nearly doubled in size since the operation.

DR. EISELSBURG of Königsberg reported two similar cases, one of sarcoma, the patient later dying from recurrence, and the other that of a child with a compound fracture. In each instance the flap included skin, periosteum, and bone, and became firmly attached.

PROFESSOR KÖNIG of Berlin showed a girl, seven years of age, in whom laryngotomy had been performed in 1892 after intubation for diphtheria had been tried and proved useless. The child had been wearing a long tracheal tube, and attempts to remove it had always resulted in severe attacks of dyspnea. In order to remedy the existing defect, four separate operations had been resorted to. Granulation tissue was first removed from between the larynx and trachea, and the trachea was freed from its attachments behind the sternum and brought up and sewed to the larynx. Two months later, at the time of the second operation, the two portions of the tube had again become widely separated; these were brought together as before, the canula being allowed to remain in place. Subsequently, two additional operations were performed in order to close the opening, skin and bone flaps in the first instance being taken from the sternum, and in the second, from the clavicle.

A son of Dr. König reported five cases of defect resulting from tracheotomy and laryngotomy, in two of which the opening had been closed by means of a skin and cartilage flap from the thyroid cartilage.

PERMANENT CURE AFTER EXTIRPATION OF THE LARYNX—

was the title of a paper by DR. GRAF of Berlin. He reported 47 cases of carcinoma of the larynx and 1 of malignant endochondroma operated upon by Von Bergmann. In all of these cases the diagnosis was confirmed by the microscope. Twenty-eight of the operations included total extirpation of the larynx, 11 extirpation of one side only, and 9 of partial extirpation. Of these, 42 were males and 6 females, the age of the patients ranging from thirty-one to seventy-two years. Tracheotomy was performed as a preliminary measure in all cases, and great stress was laid upon the importance of closing the wound from the pharynx and trachea.

Of the cases of total extirpation, 1 patient remains well after a lapse of seven years, 1 after two and three-fourths years, and 1 after one year. Cures have resulted also in 4 cases of one-sided and in 4 cases of partial extirpation.

DR. HEUSNER of Bremen exhibited a number of cases of fracture of the patella in which excellent results had been obtained by means of subcutaneous silver-wire sutures passed through the ligamentum patellæ and the tendon of the quadriceps extensor.

During the discussion which followed, KÖNIG said that the irregular fractures of the patella are unsuited to this method of treatment. He believes that the large amount of callus resulting from the procedure seriously disturbs the function of the joint. It is his own practice to cut down on the fracture and to sew the fragments together by means of catgut sutures.

ANATOMIC AND CLINICAL CONTRIBUTIONS TO THE KNOWLEDGE OF AND OPERATIONS FOR CANCER OF THE PHARYNX

was the title of a paper by DR. KRÖNLEIN of Zürich. From his own experience, the speaker had arrived at the conclusion that cancer of the pharynx is much less rare than generally has been supposed, and that it is met with as frequently as malignant disease of the tongue. He had had sixty-one cases of the affection under his charge, fifty-six being in the male sex, and all were of the flat epithelial variety. The disease, as met with in the pharynx, is usually unilateral and its course extremely rapid.

The operation for relief of the condition is performed after resection of the inferior maxilla after the method of Langenbeck. Of the fifteen patients operated upon by the speaker, ten had died from recurrence after an average lapse of fifteen months from the initial appearance of the disease, one had developed cancer upon the side opposite to that operated upon, after a freedom of seven months; three are living, the growth not having returned; and one is living, with a recurrence. Of eight patients suffering from the laryngeal form of the disease, who were operated upon through a subhyoid incision along the edge of the sternomastoid muscle, six died as a result of the operation, in one the condition has recurred, and one is living, and is well.

Following the discussion of this paper, DR. FRANKE of Braunschweig showed a patient in whom transplantation of a tendon for paralytic club-foot had successfully been performed.

DR. JORDAN of Heidelberg then read a paper on
LUPUS OF THE HAND AND LYMPHANGITIS TUBERCULOSA,

in which he stated that, as but thirteen cases of this affection have been reported, it is consequently rare. Two of these have occurred in the persons of cigarmakers, and it, therefore, is probable that local infection plays an important rôle in its causation.

FOURTH DAY—APRIL 24TH.

The proceedings were opened by the presentation of a paper by DR. PARTSCH of Breslau on

THE REPARATION OF THE INFERIOR MAXILLA AFTER RESECTION.

The speaker's method consists in the boring of two holes in the jaw, one on each side of the portion to be resected, prior to the resection, and the fastening of an aluminum plate to the jaw by means of these openings after the section has been removed. This plate does not hinder the process of healing, and when this has become complete an interdental splint of the same material is applied.

RESTORATION OF THE FUNCTION OF THE SPHINCTER ANI MUSCLE ACCORDING TO GERSUNY'S METHOD

was the title of a paper by DR. PRUTZ of Königsberg. After removal of the coccyx and a portion of the sacrum, the gut is pulled downward for a distance of about two centimeters and then twisted until the opening is closed.

It is then fastened in place by two rows of sutures. In eight cases in which this operation was performed the results, upon the whole, were good.

THE LYMPH VESSELS OF THE TONGUE, AND THEIR RELATION TO THE SPREAD OF TONGUE CANCER

was the title of the next paper, which was read by DR. KUTTNER of Tübingen. He pointed out the fact that the course of the lymphatics of the tongue is toward the submaxillary glands, toward the deep cervical glands which lie directly on the jugular vein, and also toward the glands which are located deep under the sternum. From the posterior region of the tongue the channels lead to the chain of glands lying along the course of the carotids. In cases of malignant disease of the tongue, in which removal is attempted, it is therefore extremely important to remove the submaxillary and deep cervical glands in order to prevent a possibility of recurrence. The speaker referred to the excellent work which has been done in the study of these conditions by Dr. Gerota, in Waldeyer's laboratory.

DR. GURLT of Berlin then read a paper on
STATISTICS OF ANESTHESIA.

He said that from the beginning of the year 1895 up to the present time he had been able to collect reports of 52,804 cases in which an anesthetic had been administered. Of this number 27,025 patients had been given chloroform, resulting in twenty-nine deaths, 19,856 ether, with three deaths, 4927 ether and chloroform mixed, no deaths, and 996 Billroth's mixture, no deaths.

EXARTICULATION AT THE SACRO-ILIAC JOINT

was the title of a paper by Dr. BARDENHAUER of Cologne. He reported the case of a female, forty-six years of age, suffering from coxitis and psoas abscess. The iliac artery first was tied, and the os pubes freed and sawed through. The sacro-iliac joint was then dislocated and separated. The wound was closed by means of large skin flaps. The patient made a good recovery and was able to leave her bed in eight weeks. A small fistula remains. An artificial limb has been fitted and the woman moves about on crutches.

PROFESSOR TRENDELENBURG of Leipzig, by a large majority, was elected president for the ensuing year, after which the Society adjourned.

HARVARD MEDICAL SOCIETY.

Stated Meeting, Held Saturday, April 24, 1897.

THE President, JOHN WINTERS BRANNAN, M.D., in the Chair.

DR. RICHARD FROTHINGHAM presented a case of patent foramen ovale. The patient was a male, eighteen years of age, who was markedly cyanosed. He was not a blue baby at birth, but developed this condition after sustaining a fall when he was between four and five years old. The history was somewhat obscure, but the speaker thought the condition was due to a congenital lesion. The boy was not well developed; his head was small, and he was dull and stupid. A systolic murmur was heard over the base of the heart and extending to the left of the

sternum. There was no history of rheumatism. The fingers and toes were black and presented the typical clubbed appearance. The tongue also was black. He complained of dyspnea on going up stairs and on any unusual exertion, but felt well in all other respects.

DR. DILLON BROWN read a paper, entitled
THE USE OF ANTITOXIN IN THE TREATMENT OF
LARYNGEAL DIPHTHERIA.

The author said that for therapeutic purposes diphtheria may be divided into two types: laryngeal and nasopharyngeal. In the first the danger is from asphyxia caused by obstruction of the larynx or by extension of the membranous inflammation to the smaller bronchi, while in the latter a fatal termination is almost invariably due to absorption of poisons through the lymph and blood supply. Again, in laryngeal cases the disease is rarely the result of a mixed infection, whereas nasopharyngeal diphtheria, as it is seen in practice and not in the laboratory, is frequently due to a mixed infection. The importance of this from a therapeutic point of view is evident when the difference between infection by the Klebs-Loeffler bacillus and by the streptococcus is considered. In streptococcus infection, the germ itself finds its way into the blood and viscera, but this is seldom true of the bacillus in Klebs-Loeffler infection. In one case there is only a toxin to contend with; in the other there is both the germ and its toxin. There are many unsolved problems in connection with the antitoxin treatment of nasopharyngeal diphtheria, but there can be no doubt of its almost specific value in the laryngeal form of the disease. In proof of this position, the reader gave an analysis of 991 cases of laryngeal diphtheria seen by him during the past twelve years. With but few exceptions the patients had been seen in consultation with other physicians. During the years between 1885 and 1890, 442 patients were intubated, of whom 27.3 per cent. recovered. From 1890 to September, 1894, calomel fumigation was employed, and of 295 cases operated upon, 41.6 per cent. recovered. In September, 1894, the antitoxin period began, and of 59 patients intubated since that time, 67.8 per cent. recovered. The analysis showed marked improvement after calomel fumigations were used, and the still greater success after the introduction of the antitoxin treatment. The benefit is seen not only in the larger number of recoveries after operation, but also in the increased percentage of patients who recovered without an operation.

DR. J. G. PERRY thought the paper an admirable one, because it gave a standard by which to go. The methods of preparing the antitoxin are improving every day, and we are also learning better how to use it.

THE PRESIDENT said that his experience with diphtheria had been mainly confined to hospital practice, and for that reason his conclusions might differ somewhat from those of Dr. Brown. He agreed with the reader of the paper that it is especially in laryngeal cases that benefit resulted from the use of antitoxin. He had seen, however, but few cases in which the intubation tube could be removed earlier because antitoxin had been given. In fact, there were then two patients in the hospital with which he is connected who have worn tubes for nearly a

year, although both have received antitoxin. He was not able to draw such a sharp line between laryngeal and nasopharyngeal diphtheria as Dr. Brown had done. Autopsies in fatal cases of laryngeal stenosis often show bronchopneumonia with the presence of the streptococcus and the staphylococcus in the pulmonary tissue. In other words, a secondary infection had taken place, although there was no lesion of the nasopharynx.

It was now the practice at the Willard Parker Hospital to give the full dose of antitoxin, 2000 to 6000 units, in one injection when the patient entered the hospital, instead of giving 1000 to 2000 units on the first day, and repeating the dose on the second and third days. Mild cases receive 2000 units, and septic or laryngeal cases 6000 units. Calomel sublimation was formerly much employed in the hospital, but of late it has fallen into disuse, partly because it seems unnecessary, and also because of the anemia produced by it.

DR. BROWN, in closing, emphasized the point he had made in the paper with regard to laryngeal and nasopharyngeal diphtheria being practically two separate diseases so far as treatment is concerned. It has been shown that antitoxin will clear up membrane very quickly, and the time during which the intubation tube must be worn is therefore shortened. Regarding the mixed infection observed in the Willard Parker Hospital in laryngeal cases, he believed it to be due to the conditions in the hospital, and not to the disease itself. In all city institutions there is more or less crowding of patients, and they infect each other. He referred to what had been said about calomel fumigation, and stated that it was quite true that anemia follows this treatment, but that a large percentage of cases recover in spite of the great prostration.

REVIEWS.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D. Ninth edition, revised and enlarged. New York: D. Appleton & Co., 1896.

THERE has been progress in therapeutics as well as in surgery. The eighth edition of Bartholow appeared in 1893, and three years later we have the ninth edition. In this the work has been enlarged by nearly fifty pages. These additions and alterations have been necessitated by the questionable introduction of new synthetic remedies. For the most part these medicaments are proprietary, and although they are largely used by a certain class of physicians, have not received the sanction of the official Pharmacopœia of the United States or of any other well-known authority until now. This is another potent illustration of the fact that methods in medical practice are steadily changing, and the question is constantly arising whether innovations are to be met and opposed or whether they are positive indications of the signs of the times and are to be accepted. In the Preface, Dr. Bartholow says, "In the absence of an authoritative tribunal to decide on the remedies for recognition and use, I have employed my own judgment in selecting those for treatment in this work. Time will determine the value of

those taken up for consideration; some will continue in favor, the failures will be eliminated." The whole volume is presented in the same style as its predecessors, and it will not appear strange to those familiar with the former editions.

AUTOSCOPY OF THE LARYNX AND THE TRACHEA.

Direct Examination Without Mirror. By ALFRED KIRSTEIN, M.D., authorized translation (altered, enlarged, and revised by the author), by MAX THORNER, A.M., M.D., Professor of Clinical Laryngology and Otology, Cincinnati College of Medicine and Surgery; Laryngologist and Aurist to the Cincinnati Hospital, etc., with twelve illustrations. Philadelphia: The F. A. Davis Co., 1897.

THIS translation, made at the request and with the collaboration of the author, is practically a second edition of the original German monograph. In that publication Kirstein first drew attention to a laryngoscopic method which was based on the fact that the angle usually existing between the axis of the oral cavity and that of the larynx could be changed into a nearly straight line by sufficiently tilting the chin upward and forward. This apparatus consisted of a specially designed tongue-depressor with electric light, and a head-mirror with similar illumination.

Of late Kirstein has suggested the possibility of discarding the electroscope and employing a special spatula alone. However we may be inclined to limit the applicability of this method, there is no doubt that it enables us in some cases to get a particularly good view of the posterior wall of the larynx and the trachea. Laryngoscopy is no longer the only method, although it will still be the classical one of examining the air passages for diagnostic purposes, but in endolaryngeal and endotracheal surgery Kirstein's simple method of direct inspection by extreme depression of the tongue will be of practical value in a majority of cases.

THE MEDICAL DIRECTORY OF THE CITY OF NEW YORK. Published under the auspices of the Medical Society of the County of New York. Press of Le Huray & Co., New York, 1897.

THIS annual directory appears on time, and is a welcome visitor. The same general plan has been followed in the preparation of it as in previous years except the arrangement of the names in the state lists for New York, New Jersey, and Connecticut, which have been arranged by towns instead of by counties. A medical directory like this is certainly indispensable in New York, and the separate lists necessitated by the present classification emphasizes the desirability of every practitioner in New York County becoming a member of the County Society. In the list of hospitals, dispensaries, etc., we notice that the names of attending physicians and surgeons to outpatient departments are not given.

TRANSACTIONS OF THE AMERICAN ORTHOPEDIC ASSOCIATION. Volume IX. Philadelphia: Published by the Association, 1896.

THIS annual report of the Orthopedic Association must

always be viewed as a fair index of the progress of orthopedic surgery. The contributions, to the number of thirty, speak for much laborious work though not presenting anything original.

The president's "definition of the scope of orthopedic surgery" is very elastic and would lead one to infer that the day is not far distant when fractures, dislocations, and infectious bone diseases are to be relegated to the orthopedist. With this tendency it is not surprising to see such an article as "Ingrown Toe-nail Mechanically Treated" in an orthopedic work.

The subject of rotary lateral curvature appears many times, the authors of these papers being Judson, Brackett, Roth, and Teschner. Teschner's view is the most recent as regards treatment; discarding all mechanic support he sees a panacea in the application of heavy gymnastics for a rapid cure. The unfavorable criticism was advanced mostly upon theoretic grounds.

Treatment of congenital dislocation of the hip receives mention in a brief paper by Brodhurst, and a lengthy one by Lorenz. The former expresses himself as an adherent to the open method in treating these affections; for the latter's very able contribution a perusal of the article is worthy in order to fully understand his "cure by bloodless reduction and weighting." Among other interesting articles are "Spontaneous Dislocation of Hip-Joint," and "Torticollis Due to Adenoid Vegetations and Chronic Hypertrophy of Tonsils.

PRINCIPLES OR GUIDES FOR A BETTER SELECTION OR CLASSIFICATION OF CONSUMPTIVES AMENABLE TO HIGH ALTITUDE TREATMENT. By A. EDGAR TUSSEY, M.D. Philadelphia: P. Blakiston, Son & Co., 1897.

THIS little book of 144 pages well merits the attention of all who are interested in the care and treatment of pulmonary tuberculosis. Perhaps there is no question of the treatment of phthisis which deserves as careful consideration as that of a change of the environment of the patient. This makes a correct discrimination and selection of the various so-called health localities of prime importance. To aid the practitioner in this as well as to guide him in the selection of the cases of this disease which may be treated at home are two of the features of this instructive and practical book.

A VEST-POCKET MEDICAL DICTIONARY, embracing those terms and abbreviations which are commonly found in the medical literature of the day, but excluding the names of drugs and of many special anatomic terms. By ALBERT H. BUCK, M. D., New York City. New York: William Wood & Company, 1896.

This little book is not only convenient for prompt and constant use, but is entirely reliable and contains the latest medical terms. A large number of new words have been introduced in medical terminology during the past few years, and some of the older terms have undergone significant changes. A compact book containing a record of these new words and recent changes is most desirable. This little book meets the demand quite satisfactorily.

NERVE-CELLS IN CASES OF SUNSTROKE (VAN GEISON).

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXI.

NEW YORK, SATURDAY, JULY 24, 1897.

No. 4.

ORIGINAL ARTICLES.

SUNSTROKE AS IT OCCURRED IN NEW YORK CITY DURING 1896.¹

By ALEXANDER LAMBERT, M.D.,

OF NEW YORK;

VISITING PHYSICIAN TO BELLEVUE HOSPITAL; ASSISTANT BACTERIOLOGIST TO THE NEW YORK HEALTH DEPARTMENT.

THE ten days from August 4 to August 14, 1896, will always be remembered as a period in which an extraordinary number of sunstrokes occurred in New York City. During the week ending August 15th, the total number of deaths in New York City was 1810, the largest ever known since the Bureau of Vital Statistics was established; 648 of these were reported as deaths due to sunstroke. The death-rate for the two preceding and two succeeding weeks was about normal for that season of the year, showing for this week that the heat was the disturbing cause which produced this sudden and frightful increase of deaths. This is shown by the following figures:

Deaths from all causes for the week ending August 1st,	803.
" " " " " " " " 8th,	809.
" " " " " " " " 15th,	1810.
" " " " " " " " 22d,	822.
" " " " " " " " 29th,	736.

The deaths from sunstroke for the year ran as follows: April, 1 death, a stoker in the Twenty-sixth cable-car power-house; May, 4 deaths; June, 1 death; July, 30 deaths; August, 725 deaths. Total, 765.

For the different weeks of August, the death-rate from sunstroke was as follows:

Week ending August 1st	- - - - -	5 deaths.
Week ending August 8th	- - - - -	11 deaths.
Week ending August 15th	- - - - -	648 deaths.
Week ending August 22d	- - - - -	66 deaths.
Week ending August 29th	- - - - -	1 death.

Deducting these deaths from the total deaths from all causes we see that the death-rate from usual causes was not abnormal, except during the week ending August 15th, when the heat would again account for the increase, as its effects on chronic diseases in their last stages would hurry the fatal ending. The deaths from diarrheal diseases, which usually increase with high temperatures, were not abnormally high even during the week ending August 15th. This leads us to examine more closely the various factors which made up the sum total of the weather for the ten days of August (4th to 14th) to

ascertain what were the causes which produced such an unusual number of sunstrokes.

Dr. Daniel Draper of the Central Park Observatory has kindly furnished the writer with the following facts concerning the weather for the month of August, 1896: The mean hourly humidity for the whole month of August was 73.18, 100 being saturation. From August 4th to August 13th inclusive, the hourly humidity was more often below this mean than above it, this being especially true for the hours between 10 A.M. and 11 P.M., when most of the sunstrokes occurred. The high temperature, of course, was the main factor, ranging, as it did, in the shade at the Central Park Observatory fifty-three feet above the street, from 72° to 98° F. For a few hours in the early morning, *i.e.*, from 1 to 8 A.M., on August 4th, 5th, 7th, 8th, and 13th, it did fall below 80° F., but for five consecutive twenty-four hours, August 7th to 12th, except 3 to 5 A.M. August 8th, the temperature ranged from 80° to 98° F., the mean temperature being 86.7° F., that is, 10.6° F. higher than the monthly mean, and 12.8° F. higher than the mean of the other twenty-one days of August. Fortunately, the hottest day was a Sunday, August 9th, or the death-rate would have been even greater than it was. This represents only the temperature in the Central Park Observatory, which was several degrees cooler than in the streets and tenements. The temperature in the sun during these days accurately shows the temperature of the streets. During the working hours of the day, from 8 to 5 P.M., this temperature averaged 119.3°

DESCRIPTION OF PLATE.

1. Normal cell from the anterior horn of the spinal cord, stained by Nissl's method. (Van Gieson.)
2. Normal cell from the anterior horn of the spinal cord. (Van Gieson.)
3. Cells from the anterior horn of the spinal cord in insolation, showing diminution of chromophilic plaques and changes in their shape and position. (Van Gieson.)
4. Anterior horn cell from the spinal cord in insolation, showing chromophilic plaques broken down into fine dust. Nissl and eosin staining. (Van Gieson.)
5. Anterior horn cell from the spinal cord in insolation, showing entire absence of chromophilic plaques, and changes in nuclear membrane. Nissl and eosin staining. (Van Gieson.)
6. Normal Purkinje's cells from the cerebellum. Nissl staining. (Van Gieson.)
7. Purkinje's cells from the cerebellum in insolation, showing almost entire absence of chromophilic plaques, and changes in nuclear membrane and deeply stained nucleus. (Van Gieson.)
8. Large normal motor cell from the cerebral cortex, and small normal sensory cell. Nissl staining. (Van Gieson.)
9. Degenerated cortical cells in insolation, showing almost entire absence of chromophilic plaques and deeply stained nucleus. Nissl and eosin stain. (Van Gieson.)

¹ Read before the New York Academy of Medicine, May 20, 1897.

F., ranging from 94° to 137° F., and after sunset the temperature fell but little below 90° F. till nearly midnight. With the exception of two slight showers between 11 and 12 P.M., on August 7th and 9th, no rain fell to cool the heated stones and brick walls. The prevailing winds were land breezes coming from the north and west, and were scarcely perceptible, moving, as a rule, less than six miles an hour, and measuring in force on an average but one-fourth pound per square foot during the middle of the day, and none during the greater part of the night hours. To sum up the causes of the sunstrokes, then, we have the excessive and unusually prolonged high temperature, a high degree of humidity which, however, is usual for this climate, together with the absence of any cooling breezes, making a hot, sultry, lifeless atmosphere, the main unusual features seeming to be the continuous height of the temperature and lack of movement of the air.

This is in accordance with previous experience, for sunstrokes are much less common in dry, hot climates than in more moist climates with lower temperatures, *e.g.*, in India the dry, hot winds are better borne than the moist, warm winds, even with lower temperatures. The dry, hot winds cause a more rapid evaporation of the perspiration and a cooling of the body, while damp air diminishes evaporation and the refrigerating processes. A lack of movement in the air, with a high temperature and even a moderately high humidity, would have a similar effect and prevent cooling. This could be withstood for a certain length of time, but if long continued, as it was last summer, a time would come when the heat-regulating mechanism of the body would lose its equilibrium, and, perspiration ceasing, the danger to life would soon become imminent. As has long been known, man, of all animals, can withstand the greatest variations in temperature for the greatest length of time; and a few days of excessive heat in New York has not usually caused a great number of sunstrokes, as the resistance of the body is not overcome, except in those whose equilibrium has been weakened by illness, great exhaustion, or dissipation. Previous to August 9th there are records of but fifty sunstrokes, while from August 9th to 14th there were 739, and but fifteen more on August 14th and 15th. This total of 805 cases is from the records of Bellevue, Roosevelt, Presbyterian, New York, Hudson Street, St. Vincent's, and the J. Hood Wright Hospitals; and it is due to the courtesy of Drs. F. W. Jackson, Austin Flint, Jr., W. B. James, J. P. Thornley, H. P. Loomis, L. A. Conner, Joseph O'Dwyer, and G. S. Knickerbocker that I have been able to gather together so many, and

I desire to express my sincere acknowledgments to the above-named gentlemen.

Any cause which lessens the resistance of the body to external influences may be said to predispose to sunstroke. Excesses of all kinds, such as over-fatigue or alcoholism, either chronic alcoholism or even a single alcoholic excess, predispose to it. The large number of cases in which there was a history of alcoholism, either moderate or excessive, is a most striking feature in the cases collected. The great majority of the patients were alcoholics. Clinically, the cases divide themselves into three classes: First, heat prostration; second, asphyxial or milder form of sunstroke; and third, hyperpyrexial form of sunstroke. Of the first class, there were 247 cases; these patients did not lose consciousness and did not have a rise of temperature up to 105° F.; some even had subnormal temperature; all recovered. Of the second class or milder form of sunstroke, the so-called asphyxial cases, there were 38, and all of the patients recovered. These lost consciousness, but the temperature did not rise to 105° F., and there was often a marked predominance of nervous symptoms. Of the hyperpyrexial cases, there were 520, with 132 deaths. A few of these patients retained consciousness, but all had a temperature of 105° F. or over. This division may seem arbitrary and open to criticism, but as we study the three classes in detail, we shall see that, while the difference is a matter of degree and not of kind, the distinctive and prominent symptoms of each class justify such a classification.

The majority of the sunstrokes occurred between 2 and 5 P.M. and between 7 and 10 P.M. The nationalities were most diverse; Americans, English, Irish, Scotch, Swedes, Norwegians, French, Russians, Austrians, Italians, Bohemians, Poles, Germans, and Swiss were represented. The histories show no case of a negro being overcome. The occupations were equally varied and comprised all kinds requiring severe manual labor, and also those which did not require it, such as laborers of all kinds and trades, clerks, policemen, salesmen, conductors, etc. Among the women, cooks and laundresses predominated. Direct exposure to the sun was not necessary, although such exposure did cause the largest number of attacks. Among those who were stricken while at work, the greatest number were brought in from 2 to 5 P.M. After work had ceased for the day and the individuals had had time to go home and eat supper, usually with beer, the increased oxidation and heat produced by food added to the fatigue of the day, and the still hot, vitiated atmosphere of the tenements caused the occurrence of a large number of cases between 7 and 9

P.M. In the middle of the night the bakers and firemen would succumb, and, together with those who had been unconscious for some hours, would be brought to the hospitals, thus keeping up the steady stream of patients.

Heat Prostrations.—The prodromal symptoms of the heat prostrations usually were severe headache, dizziness, and pain in the back and legs, or epigastrium, and sometimes numbness and tingling of the hands and feet. In some cases these symptoms came on suddenly, while in others they were present for twenty-four hours or three or four days before the patient came to the hospital. In some cases there was also diarrhea or constipation, with nausea and vomiting, and great thirst. The patients, as a rule, however, could sleep well at night and would wake more or less refreshed, but after getting up and going to work the symptoms would again come on and they be forced to stop. In only a few instances did the sweating cease. On admission, these patients were conscious, usually with intense headache, either temporal or occipital, and they seemed dazed, the prostration often being extremely marked. The tongue was usually clean and normal in appearances though more often moist and more or less heavily coated. A few patients showed a distinct jaundice of the whites of the eyes. The temperature in a few cases was subnormal— 97° F.; the rest had more or less distinct rise of temperature, from 99.2° to 104.8° F. In the patients with a subnormal temperature, or with one of 99° or 100° F., the temperature in a few hours gradually came to normal and remained so. After from five to twenty-four hours' rest these went out feeling well. Some others, with a temperature of 100° to 102° F., after twelve, twenty-four, or forty hours went out well, with normal temperature and pulse. The majority of these patients, having a temperature of 100° to 104° F., had a slight thermic fever ranging from 101° to 103° or from 99° to 101° , or 102° F. for two, three or five days, and in one case for fifteen days. The pulse varied from normal to 140. The frequency did not seem to be in proportion to the height of the temperature, but was more dependent on the condition of nervous exhaustion. In the case of two patients in whom the temperature was 102.2° F., in one the pulse was 72 and in the other 130. In two with a temperature of 103.2° F., in one the pulse was 84 and in the other 132. In the majority of cases the pulse ranged from 84 to 96. Respirations, as a rule, were slightly increased, usually being from 24 to 28. In some cases they were about normal; in others, 36 to 40 per minute. Of the 72 histories of this class, 64 are of men and 8 of women. This class of patients was cared for in the hospitals,

usually without any special record being kept of each case; hence, of the 247 cases reported, there are but 72 histories.

Of the asphyxial form of sunstroke, there are but 38 histories, with no deaths in which the diagnosis of the so-called asphyxial form was positive. Probably some of the cases of heat prostration unaccompanied by histories may have been asphyxial sunstrokes, but there is no record to show it. Of the 224 cases of heat-stroke at Bellevue, there were but 18 of the asphyxial type. It is evident, therefore, that this second group is by far the least common form. The premonitory symptoms of this form of sunstroke are varied. Sometimes there were no premonitions and the patients suddenly lost consciousness; sometimes this was immediately preceded by sudden dyspnea, or dizziness, or chromatopsia. In others, there [were] chills and sweating, with a feeling of fever, diarrhea, and severe vomiting, or marked and persistent constipation. In some patients these symptoms came on soon after a meal; in others, while at work in the sun. One patient, while walking quietly in the street at 11 P.M., suddenly, without prodromal symptoms, fell unconscious. In some there was a feeling of burning in the head, or headache, or feeling of "pins and needles" in the head. On admission, these patients were unconscious, at times moaning and grunting, with convulsive movements, or they had been unconscious and were partially conscious, with a most intense headache, either temporal, occipital, or frontal. The tongue was white and coated; sometimes there was a petechial rash on the body, the skin was hot, dry, or covered with sweat, the pupils normal or dilated and reacting to light, and the respirations shallow. The unconsciousness lasted till after a bath or for some hours, with delirium; one patient did not regain consciousness for twenty-four hours.

In a large majority of these patients the temperature varied between 98° and 101° F., while in five it was subnormal— 96° , 97.6° , 97.8° F. In others, there was a rise of temperature to 102° or 104° F., these also had a slight thermic fever for three or four days, or a week. In a few cases in which the temperature on admission was 100° F., it afterward rose to 104° F., and then fell to normal by lysis in from three to five days. The pulse was not as variable, or, usually, as frequent as in the heat prostrations. With the subnormal temperatures the pulse was from 68 to 104; with the temperatures of 98° to 101° F., the pulse in one case was 60, while in the others it ranged from 72 to 100. In the case of the patients with higher temperatures it ran from 100 to 132, while the respirations, though frequent, shallow and quiet,

ranged from twenty to forty per minute. There was one patient who deserves special mention. Though conscious on admission, with a temperature of 99.8° F., a pulse of 108, and respirations 24, he soon became delirious, and when the thermometer was inserted into the rectum he jumped out of bed and out of the window. He afterward said he thought that the thermometer was about to explode and kill him. After being brought back to the ward uninjured, the thermometer being taken from him, he became quiet, but the next morning when he was apparently quiet and rational, a drinking cup was given him. This he seized and broke on the side of his iron bedstead, and endeavored to cut open his chest with a jagged fragment and kill himself. He remained insane for a week, then cleared up entirely. Thirty-six hours after his admission his temperature gradually rose to 104.8° F., and his pulse to 140. After a hot bath and a cathartic, both temperature and pulse fell, and after eleven days he made a good recovery. In this class there were thirty-three males and five females. The blood of some of these patients showed changes, which will be spoken of later. The ordinary urinary analyses showed no more changes than is usually found in an equal number of alcoholic and normal individuals.

The third, or hyperpyrexial, class of patients comprised the true cases of intense sunstroke. There are 520 cases, with 132 deaths, 492 being men, and 28 women. Of these, there are 248 history records, with 80 deaths. Of the 52 remaining deaths, many of the patients were moribund and died in the ambulance or so soon after admission that no record was kept in the hospital books beyond the cause of death. It is to be regretted, of course, that of the 272 patients without histories who recovered, the histories were either lost in the hurry and confusion or were not taken by the overworked and really worn-out house staffs. The wonder is that so many excellent histories were so accurately taken, and it speaks well for the enthusiasm and conscientious devotion to their work of the various internes of the hospitals in New York city. It was often a physical impossibility to do all that seemed necessary, and the patients received all the attention and the records were neglected.

In studying the hyperpyrexial class, it is noticeable that the prodromal symptoms, when present, were often more prolonged than in the other two classes, having lasted from four to five or seven days, though there are more histories in which there were no prodromal symptoms at all. The usual prodromes were physical weakness, anorexia, often complete, great irritability and restlessness, insomnia for three or four days, nausea and diarrhea or constipation.

One patient had marked increase of micturition for several days. Just before consciousness was lost, sweating ceased, and there was a sensation of intense heat all through the body or only in the head, with a feeling as if the head would burst open, and as if the eyes were bulging outward. In some cases there was dimness of vision, or everything seemed blurred; in others there was chromatopsia, and all objects were blue colored or red, yellow, or white, blue predominating. One patient saw innumerable yellow flames. Some patients said everything appeared black. Three patients complained of cramps and involuntary contractions of the muscles of the body and extremities; one that his feet were beyond control. These prodromal symptoms were more common in patients in whom the temperature did not rise above 108° F. than in those with higher temperatures. Those who had the higher temperatures either had no prodromes or remembered but little more than not feeling well, with anorexia, insomnia, and vertigo, for a few days, sometimes with chromatopsia just before they lost consciousness, and their next conscious realization was after the bath in the hospital. In several instances the friends said that the patient had kept at work long after he had ceased to answer questions or had noticed anyone or anything about him. One patient started for home at 10 A.M., returned to his work, changed his clothes, again left for home, and after arriving there, took a bath and went out again. He was picked up in the street unconscious at 5 P.M. and brought to the hospital, and did not regain consciousness till 2 A.M., or nine hours after his ice bath. He remembered nothing except leaving for home at 10 A.M. Another took a car and started for the hospital but stopped at his home, and later went out and brought in a pail of beer. He was brought to the hospital and remembered nothing after first starting for the beer. Another remembered leaving Hoboken on the Christopher street ferry-boat but nothing more, though he was picked up at Fifth street and East river, over two miles from where he had landed. Although apparently unconscious of their surroundings, these patients were able to perform complex acts in an apparently voluntary and rational manner.

The symptoms on admission varied somewhat. In every instance in which the consciousness or unconsciousness of the patients is mentioned, and in which the temperature was 110° F., or over, coma was complete. In one patient whose temperature was 109° F. consciousness was sufficiently retained so that he could be partially roused. With temperatures of 108° to 109° F., 1 patient was conscious, 3 partially so, and 30 unconscious; with temperatures 107° to 108° F., 6 were conscious and 21 unconscious;

with temperatures 106° to 107° F., 8 were conscious and 21 unconscious; with temperatures of 105° to 106° F., 11 were conscious and 11 unconscious. Those that were conscious complained of intense heat and headache. One patient walked into the hospital, with a temperature of 105° F., asked for the cold bath, and helped himself into it and out of it.

The unconscious patients presented a striking picture. Their skins were dry, hot, and flushed, or cool, pale, and livid or cyanotic, with a clammy perspiration, their eyes suffused and half open, or staring and filmy. The pupils were dilated, contracted or normal, or unevenly dilated or contracted; sometimes they reacted to light, sometimes they would not react. In addition, their mouths were open, with lower jaw twitching convulsively, and their respirations came in short gasps, with either a noisy, gasping inspiration and quiet expiration, or a quiet inspiration and explosive expiration, each expiration at times being accompanied by a piteous moan or groan. Sometimes they lay absolutely limp and flaccid, or with their muscles twitching convulsively or even in general convulsions. Often they were wildly delirious and fought and struggled furiously. The pulse was rapid, very frequent, and small and thready, or full and strong, with throbbing carotids; in the worst cases, they were pulseless. In many cases there was a petechial rash on the body and extremities, or only on the body. The patients emitted a peculiar, disagreeable odor quite distinct from that of fecal matter, though the discharges of the involuntary defecations and urinations, which almost always occurred, were of the most offensive character.

The temperature of the patients on admission, in the 246 cases in which it is mentioned, was as follows:

117.8° F.	1 died; New York Hospital	-	-	Total	1
115° F.	0 died; 1 recovered, Presbyterian Hospital	-	-	"	1

The pulse, on admission, showed no regular variation with the temperature, for from 105.4° to 112° F. it had the same frequency and varied with all degrees of temperature, e.g., temperature 105.4° F., pulse 150, respiration 50; temperature 105.4° F., pulse 100, respiration 24; temperature 110° F., pulse 90, respiration 38; temperature 110° F., pulse 150, respiration 50. The quality of the pulse was the best indication of the patient's condition, as sometimes a pulse of 144 would be of good quality and strong, or feeble and small. The frequency and

quality bore no regular relation to the temperature or respirations.

The following table shows this more in detail:

Temperature.	Pulse.	Respirations.	Cases.
117.8° F.	180	64	1
112° F.	160	40	1
110° F.	90 to 150	16 to 50	12
109° F.	116 to 160	30 to 50	11
108° F.	112 to 160	20 to 44	9
107° F.	100 to 162	18 to 52	8
106° F.	96 to 160	18 to 50	16
105° F.	96 to 150	16 to 50	10

Total, 68

The averages of the above table are as follows:

Temperature.	Pulse.	Respirations.
110° F.	132.3	31.6
109° F.	151.2	38
108° F.	138	32.6
107° F.	128.8	34.6
106° F.	135.6	30.9
105° F.	111.3	29.1

During the administration of the bath or cold pack, or within an hour afterward, about one-half of the patients became conscious, and usually remained so. Others did not become conscious after the first bath, but after their temperature rose again and a second bath was given, consciousness returned and they remained rational. Many patients did not regain consciousness until the day following the attack, some not until three or five days, and one not for ten days, and then recovered. Many with a temperature above 108° F. did not regain consciousness at all, and though the temperature came down, the pulse remained frequent, dyspnea and cyanosis often being marked, and such finally died. These patients usually died during the first twenty-four hours after admission; some lived forty-eight hours or more, while one lived six days. There were several patients who became conscious immediately after the bath, or after a few hours, and remained so from four to nine hours or more, often from one to two days; then they again became unconscious, with marked delirium, and remained in this state from two to seven days, and then recovered. A few of these, however, died during the delirium. The patients who came into the hospital in convulsions usually continued to have these even after their bath. It was commonly a tonic spasm, with intermittent clonic convulsions general in character, though sometimes confined to the arms or legs or head and neck. One patient had left-sided convulsions of the face, arm, and leg, and these continued for some hours until he died. A marked rigidity of the muscles without convulsions was not uncommon. These convulsive seizures were very common, and sometimes were controlled by a second bath, but not usually so. At times they would disappear and return twenty-four hours later, or even two or three days after the patient had become conscious and quiet. A few patients died suddenly in

a convulsion twenty-four hours after consciousness had been regained.

The fall of temperature after the bath was followed in the case of a majority of the patients by one or more secondary rises. This rise occurred in all in whom the initial temperature was over 110° F., if they did not die with the fall of temperature which accompanied the bath or cold pack. In a few patients, with a temperature from 107° to 110° F., there was no marked secondary rise above normal, and they went on to an uninterrupted recovery. In patients with a temperature of 105° to 107° F. this was a common occurrence. In most patients who did well, one or two slight secondary rises was the rule, the two rises being less common than the single rise. Some patients recovered, though their fever curve showed three to four, and even five, marked rises. Those patients who succumbed usually did so upon the first or second rise, or failed to react after the two or three baths given to reduce these exacerbations. Some, however, had three, four, five, or more secondary rises before they died. One patient, with an initial temperature of 108° F., had nine exacerbations up to 104° or 105° during forty-eight hours before he died.

The first rise occurred most frequently three to six hours after the first bath, next in frequency after twelve to eighteen hours. In bad cases the rise often occurred within the first three hours, sometimes within an hour. The second secondary rise occurred most often twenty-four or thirty-six hours after the bath, next often from twelve to eighteen hours afterward. In bad cases this second rise would occur in two or three hours after the first secondary rise, and from three to eight hours after admission; that is a majority of the patients required the taking of active measures to reduce their temperature three times during the first twenty-four hours after admission. The third rise occurred in the ninth or twelfth hour, or during the second and third day after admission, and the fourth and fifth rises during the second, third, or fourth days. Many patients had more or less of a thermic fever, which was not high enough to require interference, the temperature ranging from 103° to 101° or 100° F., and lasting from three to five or from seven to ten days, and in some cases even two or three weeks. In some cases the fever averaged a little higher and the patients required sponge baths. The pulse, after the temperature had fallen, improved in the patients who recovered, both in its force and frequency. As a rule, it fell to normal more slowly than the temperature. After a few days, however, even if there was a moderate thermic fever, the pulse usually averaged about 80 or 90. In the fatal or very severe cases the pulse remained rapid

and frequent, was apt to be thready, and was usually feeble and soft.

The examination of the blood showed a decided leucocytosis. The red cells were distorted and sometimes apparently shrunken, and the leucocytes contained pigment. The hemoglobin color-test in the case of twelve patients showed 85 to 125 per cent., and averaged 100 per cent. This is far above the average, and was due to the free hemoglobin in the blood from destruction of the red cells. The subsequent anemia in nearly all the patients was very marked.

Some patients had bloody expectoration during the administration of the bath and for awhile afterward; a few had bloody stools.

Retention of the urine was not an uncommon symptom. The specific gravity of the urine of the first twenty-four hours seemed to be lower than normal and to contain a lessened amount of urea. In seventeen samples the amount of urea was above normal in two, normal in one, and in fourteen below normal. The urine of the same patients, from five to ten days later, was usually of higher specific gravity, and contained the normal amount of urea. These few observations do not justify any sweeping conclusions, but the facts were sufficiently noticeable to be striking. Often the urine was normal; often it was of low specific gravity, due to chronic Bright's disease, but in these cases it remained the same after recovery from the attack.

The fatal complications observed were meningitis, pneumonia (one with sacculated empyema), and acute exacerbations of chronic kidney disease, which gave rise to suppression of the urine or to dyspneic attacks, with emaciation. The cause of death in most cases was simultaneous failure of the respiratory and cardiac centers. In some instances a sudden rigidity of the respiratory muscles, and in fact of the whole muscular system, caused suffocation. This rigidity was so intense that artificial respiration was impossible. When respiration ceased before the heart, and artificial respiration could be performed for one-half to one hour, it sometimes saved the patient. In other patients the heart stopped first and nothing would stimulate it.

The immediate sequelæ of sunstroke were headache, extreme weakness and malaise, dizziness, soreness in the muscles and bones, and frequently numbness and tingling in the hands and feet. This tingling lasted for days, and in some cases for two or three weeks; in one case it was present for two or three months. The anemia was usually extremely marked. Two patients developed incoordination of the extremities, which has remained permanent. One patient had attacks of vertigo and fainting,

which confined him to bed for two months. At present he has complete atrophy of the right trans-versus pollicis muscle and loss of power in the flexor muscles of the right forearm, his hand being so weak that he can scarcely hold a pen. Three patients developed delusional insanity; two of these recovered and were apparently normal after from six to eight weeks, while the other left the hospital still suffering with delusions.

Dr. R. M. Daley of the Bellevue Hospital staff has endeavored to trace for the writer all the patients that were treated last summer for heat-stroke at Bellevue Hospital. He has been able to obtain the following facts: Number of patients found nine months after the sunstroke occurred, 73. There were no sequelæ in 42. Three had become insane, and 13 suffered from attacks of dizziness and were more sensitive to heat. Five had frequent severe headaches, which they had not had previously. Chromatopsia on hot days was present in 1, and gastritis in 1. One patient had a changed disposition; formerly having been good-natured, even when drunk, he is now ugly and irritable, especially when drinking. One patient for a period of two months felt a numbness of the whole body, though he could easily feel a pin prick, etc. Numbness and weakness of the hands and feet, which persisted for three months, occurred in two cases, and the same conditions persisted after nine months in another. One patient had an increased number of epileptic attacks since the occurrence of the sunstroke and was re-admitted to the hospital six weeks after his sunstroke, with polyuria and glycosuria, which had appeared since his attack. Dr. Van Gieson has given me the report of one of the sunstroke cases from the New York Hospital. Within two months after the patient's seizure she developed multiple neuritis and dementia and two months later died with dementia. One patient insists that his eyesight has been much improved since he suffered the sunstroke.

There was a peculiar asthenic condition noticed in a few patients which deserves special mention. Among the Bellevue Hospital records there are five such histories occurring in the services of Dr. Jackson and the writer. While similar cases probably occurred in other hospitals, the records at the writer's disposal do not mention them. Four of these patients had an initial temperature of 106.2°, 106.4°, 108.2°, and 109° F., respectively, that of the fifth not having been recorded. They all reacted well after the bath and became conscious, either immediately or within four hours, and remained rational for twenty-four hours. They then became delirious, three of them wildly so at first, fighting everyone who came near them, and then sank into a low,

muttering delirium. Two developed low delirium without having passed through the previous wild stage. Their skin was dry and harsh, their emaciation rapid and extreme; and they had incontinence of urine and feces. Their half-closed eyes, hollow, sunken cheeks and extreme general emaciation, in a few days presented a striking picture compared with their well-nourished appearance on admission. During the wild delirium their temperature rose to a high point, frequently equaling the initial rise, with a pulse ranging from 120 to 150, but at first, during the stage of low delirium, the temperature of all five patients was from 99° to 102° F., and the pulse from 80 to 100. Finally, the pulse again became frequent (120 to 130), and the temperature, in three cases, rose ante-mortem, to 106° and to 110° F. In two cases the temperature did not rise. These five patients died ten, three, six, eleven, and eighteen days after the seizure. They were all markedly alcoholic, and probably this factor had a controlling influence in the course of the disease. In these cases, however, during the wild delirium, the temperature rose to a much higher point than is usually observed in delirium tremens, and the extreme emaciation was more rapid and marked than is usual in the low, muttering delirium met with in the ordinary cases of so-called alcoholic "wet brains."

Another sequel alluded to, that of dryness and harshness of the skin, was present in a great many of the cases of hyperpyrexia. Usually two or three days after the sunstroke the skin over the whole body became dry and harsh and finally peeled off in fine particles or in large flakes.

Ecchymoses were common in the patients who bruised themselves during their delirium or during their convulsions. These ecchymoses were much more extensive than is usual in the case of ordinary bruises. Hypodermic injections frequently caused ecchymosis, and if Hoffman's anodyne or aromatic spirits of ammonia had been used, small abscesses often followed. These healed rapidly under the application of ichthyol.

It is interesting to note that six patients gave a history of having had a heat-stroke some years previous to the one during August, 1896. In one instance this had occurred twenty-eight years before, in one, five years, and in four, "several years." All these patients recovered from the more recent attack. Six patients were re-admitted to the same or to different hospitals upon the recurrence of sunstroke within ten days, and while four of these recovered, two died.

The treatment of sunstroke at the various hospitals during August, 1896, differed so much in essential details that we have an opportunity of judging as to which appears to be the best. This is especially

true, as all of the hospitals treated at the same time exactly the same class of patients and the same types of the disease. The heat prostrations were treated alike in all of the hospitals. The patients were put to bed, and if necessary given a cool sponge bath, and phenacetin or some such drug for the headache. This, with rest, was all that they required. Sometimes an ice-cap applied to the head gave great relief. The asphyxial class of patients were given tub baths at 60° F., or sponge baths, or if the coma and nervous symptoms demanded it, they were put for a few minutes into an ice bath and thoroughly rubbed, being taken out when the body temperature fell a degree or two. They were stimulated with drugs when necessary, but for the most part they required little more than rest and quiet and the stimulation of a cool bath. But it is in the treatment of the hyperpyrexial cases that the true test of sunstroke treatment is to be made. There is no disease which demands more immediate and active treatment, or which will respond more satisfactorily when proper measures are instituted. Hydrotherapy in some form was tried in all cases. It differed in the method of application and the temperature of the water employed.

The records of mortality at the various hospitals furnish a fair estimate of the efficacy of the different methods of treatment. The mortality among the patients treated with ice baths, the bath being continued until the body temperature had fallen to about 103° or 102° F., varied in the different hospitals from 18 to 27.5 per cent. When the ice pack was used in some cases instead of the ice baths, the mortality was 25.5 per cent. When the ice bath was given for ten minutes, irrespective of the point to which the temperature fell so long as it remained above a safe limit, the mortality was 40 per cent.

Among the patients treated by means of baths ranging in temperature from 50° to 75° F., the mortality was 33⅓ per cent.; when the baths were given at a temperature of from 90° to 110° F. and reduced in from fifteen to twenty minutes to 72° F., as was done at the Brooklyn Homeopathic Hospital, the results do not seem to have been as favorable as with the cold baths. Judging from a published article,¹ at this hospital there were 49 heat cases of all kinds treated; 17 of the patients were unconscious, and 7 were wildly delirious; nine died, 2 living for only five and six minutes respectively after admission. It seems fair to say, therefore, either that all of the 7 patients who exhibited severe symptoms died, or else that in the case of 17 patients who were unconscious, with high or moderately high temperatures, there were 7 deaths, or a mortality of 41.17 per cent.

¹ *The Chironian*, February 1, 1897, p. 98.

Among the patients treated with a needle spray from a hose attached to a cold-water faucet, the mortality was 11.5 per cent. In St. Vincent's Hospital, in which the treatment was that of cold packs followed by hot packs, among 197 hyperpyrexial cases the death-rate was 12, or 6 per cent. Counting in the 8 patients who died a week or more later, the mortality was but 10.15 per cent. The death-rate of sunstrokes as given in Quain's "Dictionary of Medicine" is from 41 to 50 per cent. In the 926 cases reported by Aiken,¹ the mortality was 421, or 56.62 per cent. Of the 520 cases of hyperpyrexial sunstroke, with 132 deaths, recorded in this paper, the mortality was 25.38 per cent. Among those patients who lived long enough to be treated, the mortality was 25.12 per cent. The treatment employed in the various hospitals of New York City, therefore, certainly gave satisfactory results. If we consider the various methods more in detail we can arrive at a fair judgment of which method of treatment promises the best results.

By an ice bath is meant a tub bath in which ice, crushed into moderately sized pieces, is constantly kept floating. The temperature of the bath is about 40° F. This method of treatment has its advantages and its disadvantages: The advantages are that it is a sure and rapidly effective means of reducing the body temperature and is a powerful stimulant to the nervous system. The ice should be removed from the tub before the patient is placed in the water, and after a minute or two from half a bushel to a bushel of cracked ice should be poured in; or, if there is only time in which to prepare the bath, the patient should be placed in the water and the ice be added. If the patient is lowered into a bath with the ice remaining in it, especially if it has been standing for some time, the shock is too great, and some patients as soon as they touch the ice become rigid, respiration ceases, and they cannot be revived. This, fortunately, is rare, but it does occur, and should be guarded against. This rigidity does not occur if the ice is added after the patient is in the water.

The head of the patient during the bath should be supported and constantly bathed with the ice water, care, of course, being taken to keep the water out of his eyes and face. Incessant and vigorous rubbing of every portion of the body is an absolute necessity. This must be kept up during every moment the patient is in the bath. The rectal temperature should be taken every minute or two, and when it falls to 104° or 103° F. he should be lifted out, placed in a blanket, rubbed dry, and allowed to rest. Stimulants should be given as the pulse may indicate. It was noticed that if the temperature was allowed to fall

¹ Aiken's "System of Medicine," vol. ii.

below 102.5° F. during the bath, it was apt to continue down to a subnormal point, and depression, instead of stimulation, was the result. After a subnormal temperature, the second rise was apt to occur sooner and be more intense than when the temperature had fallen to normal. When such baths were properly given, the pale and livid or cyanotic color of the skin soon changed to a bright red, and the pulse, and especially the respiration, improved, and sometimes consciousness returned even in the bath itself.

The length of time necessary to reduce the temperature varied so much with all temperatures that no regular duration can be given; the time was usually judged by the fall of the temperature, though a few patients did not bear the bath well, and were taken out before the temperature was reduced to 104° F. When the bath was given for ten minutes, irrespective of the height of the body temperature, the results were not good. In the case of some patients, even those with the highest temperature, the fall was so rapid that ten minutes was too long, while in a majority of the cases the time was not sufficient, and the temperature after the bath, instead of falling to near normal, did not fall below 106° or 104° F., and it soon rose again so that after the lapse of an hour another bath was required. The overheated body and viscera had not been brought sufficiently near the normal temperature to enable the organs to resume their functions. The opportunities for recuperation were therefore greatly diminished.

The disadvantages of the ice bath are that it requires a large staff of assistants to hold a struggling patient, and to rub him as thoroughly as the circumstances demand. It is tiresome and painful to those giving the bath. Six or eight assistants are required to each tub, and when two or three baths are being giving at one time, as was the case for hours at a time at Bellevue, these disadvantages are increased. A large amount of ice is necessary, and an adequate amount may not always be at hand. For example, 20,000 pounds were used at Bellevue Hospital from August 9th to 13th for the ice-water baths alone.

The ice pack was given by placing a patient on a rubber sheet and packing large pieces of ice along and between the legs and along the sides of the body. The upper surface of the body was then rubbed with the hands and with pieces of ice. This procedure often required more than an hour to reduce the temperature. When it was employed, the temperature was allowed to fall to 101° F., and it almost always went to 96° or 95° F. This method does not permit of the necessary amount of friction being applied over the whole body. The writer saw it used extensively when he was an interne at Bellevue Hos-

pital, and is convinced that it is not as stimulating as a cold bath, and, therefore, not as efficacious.

At the Flower Surgical Hospital, as reported in the *Hahnemannian Monthly*¹, a method of procedure was followed which seemed to be excellent. The patient was stripped and put on a cot covered with a rubber sheet, an ice cap was applied to his head, and three sections of hose with nozzles giving a fine needle spray were fastened to cold-water faucets and the patient vigorously sprayed until his rectal temperature was reduced to 103° F. The patient was then wrapped in two blankets. If a secondary rise to 104° or 105° F. occurred, the spraying was repeated until the temperature fell to 101° F. There were twenty-six patients thus treated, their temperature averaging 108° F., and of these but three died, a mortality of only 11.5 per cent. The needle spray is a tremendous nervous stimulant, and with tap-water at 75° F., there is no sudden shock. This method is so excellent and is founded on such sound principles that it deserves widespread recognition.

At St. Vincent's Hospital the treatment was as follows: The patient wrapped in a cotton sheet, was placed on a stretcher, covered with a rubber sheet. Dipperfuls of cold water were forcibly dashed on him from a distance of several feet. In the very severe cases, every two or three minutes a small stream of very cold water from a pitcher was allowed to fall from a height of six or eight feet and strike the patient on the forehead between the eyes. This treatment proved to be powerfully stimulative, and was continued until the body temperature fell to 104° or 103° F. The patient was then wrapped in blankets and surrounded by hot bottles. The body temperature fell slowly to normal, and no marked reaction occurred. Often after a short interval, the warm pack brought on sweating and the patient slept. When a second rise of temperature occurred, the procedure was repeated. Cold water and whisky were given upon awakening. Digitalis and liquor ammonii acetatis were about the only stimulants used. The convulsive seizures were controlled by whiffs of chloroform. The giving of strychnin was avoided, as it was believed it increased the convulsions. Of the 197 hyperpyrexial patients thus treated, only 12 died, or 6 per cent. Eight others returned a week later and died of meningitis, etc. Including all the deaths, as has been done in the records of other hospitals, there was a mortality of but 12.15 per cent., by far the best results obtained. This plan of treatment was suggested by Dr. Joseph O'Dwyer and was carried out by his house physician, Dr. C. F. Chandler.

Drugs, when administered in their usual doses, did

¹ January, 1897, p. 61.

not appear to act, and it seemed to the writer that until the temperature fell below 104° or 103° F., they had very little if any effect, either in stimulating the heart or quieting the delirium. Those which seemed to stimulate the best were camphor in ether, caffeine, Hoffman's anodyne, digitalis, whisky, and strychnin. Alcohol in some form was often necessary, and was usually well borne. In the most pronounced cases of delirium and convulsions, the best sedatives were morphin and small doses of hyoscin. Trional also acted well, and even in large doses produced no ill effects, one man taking as much as 100 grains during twenty-four hours. The sequelæ (malaise, weakness, and loss of appetite) were best treated by the administration of a mixture containing from 5 to 15 minims of the tincture of nux vomica, and from 10 to 20 minims each of the compound tinctures of cinchona and gentian three times a day. In patients in whom a sudden rigid spasm of the respiratory muscles and a general muscular rigidity occurred, one or two drops of amyl nitrate dropped on the mucous membrane of the nose relaxed the spasm. One or two patients treated in this manner recovered after they were thought to be dead. This treatment was also effective in sudden collapse. Artificial respiration practised for half an hour to an hour after breathing had ceased, succeeded in some cases in causing it to be re-established, and some of the patients recovered.

The advisability of bleeding sunstroke patients has long been a mooted question. Most authors strongly condemn the practice except in a very limited class of patients, such as large, full-blooded men with a marked tension of the pulse, throbbing arteries, and wild delirium. The writer saw it tried on two such patients at Bellevue Hospital, with beneficial effects. In some other less sthenic cases it did not appear to do good, and it is a question if it did not do actual harm.

Ice-water enemata were used in many cases at Bellevue Hospital, with excellent results. This treatment was especially beneficial in the case of patients who were conscious on admission, with a temperature of 106° to 107° F. Within an hour after the enema the body temperature had fallen to 100° F., and in some cases it did not rise again. Sometimes the ice-water enema was used to control the secondary rise of temperature, but it did not prove very effective for this purpose. When the patients were unconscious the enema did not produce the same amount of stimulation as the cold bath with friction, and was therefore not as beneficial, and in fact it did not control the rising curve of the temperature, as well as the cold sponging or cold baths.

Japanese ice-bladders filled with ice and placed

in the axillæ and on the groin of patients with thermic fever, whose temperature ranged from 103° to 105° F., controlled the fever sufficiently, and if additional cold was needed, the cold coil on the abdomen was of great assistance. These means were especially effective with women. When the number of baths to be given was a serious consideration, these simple methods were of considerable help.

The best treatment, therefore, seems to be the application of a needle spray, ice bath, or cold pack until the temperature falls to 103° or 104° F., followed immediately by a hot pack with stimulants and sedatives, as one's judgment may deem necessary.

A brief summary of the pathology and causation of sunstroke is all that the limits of this paper will permit. The gross pathology has always been conflicting, and the changes found are not characteristic of any definite and uniform lesions. It seems that we must finally turn to cellular pathology in order to study the changes in the cells themselves and in order to learn, if possible, both the cause and its effect. The clinical symptoms also indicate this. The prodromal symptoms are those of acute functional disturbance, and the serious later symptoms show that there are grave changes in the blood and in all the nervous centers, especially those which rule and hold in stable equilibrium the heat-controlling mechanism of the body.

Dr. Ira Van Gieson, Director of the Pathological Institute of the New York State Hospital for Lunacy, has kindly furnished me with the following report of the changes in the nervous system in three cases of sunstroke. This is but a preliminary report on a series of fifteen cases which occurred during the summers of 1895 and 1896. He has allowed me to anticipate his more detailed notes on the pathology of sunstroke, which, with more extended clinical observations by the writer, will appear in a future issue of the *New York State Hospital Bulletin*. Sections have been examined from the spinal cord, cerebellum, and various portions of the cerebrum, such as the caudate nucleus, optic thalamus, lenticular nucleus, paracentral lobule, cornu amonis, and middle portion of the second frontal convolution. All these sections show more or less pronounced changes in the chromophilic plaques of the ganglion cells. These plaques in some cells are changed in shape and are fewer in number; in others they appear to be broken up into fine dust, and, again, in others have even entirely disappeared. The nucleus stains more deeply with methylene blue than it should normally, and within the nuclear membrane there are some minute spherical granules which are not normally present. As the chromophilic plaques show the potential energy stored in the cells, and any

changes in the nucleus may be said to be directed against the life of the cell, it will readily be appreciated how extensive are the changes which have occurred. In the drawings which Dr. Van Gieson has prepared, a comparison with the normal cells from these regions will indicate these changes better than a description does. His deductions from these changes are as follows:

"We have found in these three cases a universal exhibition of acute parenchymatous degeneration of the neurons of the whole neural axis. In the cerebral cortex and in the cerebellum the cells show the same stages of degeneration. The spinal-cord cells apparently are not as extensively involved as those in the cortex and cerebellum. There seems to be no other interpretation open as to the significance of this degeneration than the operation of a toxic substance upon the ganglion cells. There is a resolution of the elements of the ganglion cells as an exhibition of the chemic reaction between a poison on the one hand and the constituents of the cell on the other. This toxic resolution of the ganglion cells may not necessarily go on to the destruction of the cell, and is compatible with restoration and recovery of function and structure. This depends, however, upon the cessation of the poisons. In other words, in insolation there is toxic cytolysis or cell resolution of the neurons, which depends upon the condition of the body forces, the eliminative capacity of the body, and the strength and duration of the poison. Depending on these three factors, the neural parenchymatous degeneration may result in restoration or destruction of the neurons involved. I have no hesitation in accepting the toxic agency of insolation from the morphologic changes in the ganglion cells, because I find that such changes are in every way similar to those produced by the operation of a great variety of other poisons, including the extrinsic group, such as alcohol, lead, etc., and the microbian poisons and other intoxications, both in human diseases and in those produced experimentally in animals. Furthermore, by the method of elimination in excluding other groups of poisons, I feel justified in concluding that sunstroke is a species of auto-intoxication, and that the neural symptoms find a clear and definite explanation in the acute parenchymatous degeneration induced by an autogenous poison."

The nervous system of one of these three patients was from a boy in whom alcohol can be surely excluded.

While the autotoxic basis of sunstroke, with heat as a contributing cause, has previously been suggested, to Dr. Van Gieson should be given the full credit of placing this theory on a more definite, tangible basis by finding parenchymatous degeneration

of the nervous system similar to other toxic degenerations of this tissue, and by stimulating the chemico-physiologic experiments of Dr. Phœbus Lèvene, Associate in Physiologic Chemistry at the Pathological Institute, in his demonstration in animals of the toxic properties of the body fluids in insolation.

Ten years ago, Vincent, in France, as a result of experimental work, came to the conclusion that the exaggerated elevation of temperature acts principally on the central nervous system, but in an indirect manner.¹ In other words, it is a poisoning of the economy by the products of combustion which accumulate in the blood. The morbid trouble provoked by hyperthermia is the expression of an auto-intoxication which, after having a general excitation of the central nervous system, brings on its final destruction. On the other hand, Wood² and Laveran,³ and many others, consider that all the changes and symptoms are due solely to the excessive amount of heat in the body.

Let us first consider the mechanism of sunstroke from the standpoint of its causation by heat alone. The normal body can and does resist any undue decrease or increase in its temperature as long as the equilibrium of the heat production, distribution, and loss, is maintained. This is accomplished by the contraction or dilatation of the skin capillaries, and by a decrease or increase of the perspiration, with the consequent decrease or increase of the loss of heat from the skin. It is also supposed by some authors that certain cerebral centers preside over the heat regulation by inhibiting production. Heat is produced by the chemic metabolism constantly going on in the body, and is especially generated during muscular action. Two and six-tenths per cent. of the heat is lost from the body by warming the substances taken in as food and drink, 2.6 per cent. by warming the inspired air, 14.7 per cent. by evaporation, and 80.1 per cent. by radiation and conduction from the skin. During such weather as was experienced last summer the loss of heat by cooling inspired air which was already three-fourths saturated with vapor and often hotter than the body, would practically be nothing. Radiation and conduction from the body to hotter air would also be abolished, and over eighty per cent. of the sources of heat loss would be withdrawn and the body would have to depend on evaporation for its loss of heat. If the air should be nearly saturated with vapor, and no air be stirring to renew that in contact with the body, it is readily seen that if such conditions should be long

¹ Vincent, quoted by Laveran, *Bull. de l'Académie de Médecine*, 3d series, Vol. 32, 1864, p. 501.

² Wood, "Sunstroke," 1872; also, Pepper's "System of Medicine."

³ Laveran, *loc. cit.*

continued, and if large amounts of heat were produced by muscular action, the strain on the regulating centers would be severe. Should these centers be weakened in any way by previous illness or dissipation, they would soon succumb, and heat accumulating quickly, some form of sunstroke would supervene. If sweating ceased, as it usually does in sunstroke patients, just so much quicker will all heat loss be in abeyance, and all the heat produced be stored up and the danger to life be imminent.

Increased heat causes increased oxidation and more heat; an increase of oxygen being demanded, the respirations would increase and the pulse-rate quicken under the stimulation of the heart by the heat. If the resistance of the patient should be great, or the exposure to heat not excessive, the patient would suffer from heat prostration, which is but the prodromal period of the asphyxial or hyperpyrexial forms, if the resistance should be less, or the exposure more severe, unconsciousness might come on and the asphyxial form develop, with a paralysis of the vasomotors which would prevent a great rise of temperature, for, as is well-known, vasomotor paralysis causes a dilatation of the skin capillaries and a consequent fall of temperature, due to the sudden increase in the loss of heat. If, however, exhaustion occurs, with an accumulation of heat so excessive that the heat loss would not counteract it, the great production and accumulation of heat would give rise to the hyperpyrexial form. The blood changes and all the changes in the body will be caused by the excessive heat, and death will ensue when these changes are such that the nerve-centers can no longer functionate.

But does heat cause a cessation of sweating, and how? Is it a parenchymatous change in the sweat glands, due to exhaustion from excessive action and consequent cessation of function, or is it a cessation of action caused by the effect of heat on the nerve-centers governing the secretion? It is not due to changes causing non-conduction in the nerve-fibers, for these will conduct perfectly at a temperature of 125° F.¹ As yet no experiments have been successful in solving this question. The cessation of sweating in other fevers we believe to be brought about by the cause of the fever, not by the fever itself, *i.e.*, by the temperature *per se*. In the severe cases of sunstroke there is a vasomotor constriction, not a dilatation as most authors claim. This is proved by the cold, pale skin when the rectal temperature is 109° F., or more, and this constriction of the skin vessels in other fevers is also produced by the causal agent, not by the temperature. Will the theory, therefore, of some poison or poisons circulating in

the blood, *i.e.*, the auto-intoxication theory, better explain the clinical symptoms? The heat and concomitant factors of the weather are undoubtedly contributing causes, just as exposure to cold is the contributing cause to ordinary lobar pneumonia. The effects of heat on the body, as shown by the prodromal symptoms, are shown in disturbances in the glandular and digestive functions of the body. The chemic metabolism of digestion is not normal, and substances may be produced which, in the disturbed functional activity of the liver and other glands, are not properly and normally broken up, or there may be abnormal substances produced by the disturbed condition of the digestive apparatus, which are absorbed. These different substances carried over the body are not excreted because of the functional disturbances of the emunctories, and, by the intense and rapid action of these substances or by their slower and more prolonged action on the ganglion cells of the central nervous system, produce the changes described above. There will, therefore, first be symptoms of functional disturbances, followed by those of destructive action. The equilibrium of the heat-regulating centers will be disturbed because these centers will themselves be affected. The same external causes affecting heat loss will be present, and the same train of events will occur as though heat alone were the sole cause.

Many patients die of sunstroke with a temperature which, in other fevers, would not be unusual and do not cause death. For example, one patient came into Bellevue Hospital with a temperature of 102.8° F., a pulse of 116, and respirations 22, perfectly conscious and rational. Four hours later he had become delirious and unconscious, his temperature being 103° F., pulse 132, and respiration 32. A bath brought the temperature down to 100° F., the pulse to 100, and the respiration to 22. Three hours after the bath his temperature was 100.8° F., pulse 90, and respiration to 20; and four hours later he was wildly delirious, his temperature having risen to 105.4° F., his pulse to 120, and his respirations to 30. After another bath his temperature fell to 96.4° F., and in spite of stimulation he died. The subnormal temperature does not seem sufficient to have caused death. It would seem that the cause which produced the wild delirium and unconsciousness, with the rapid heart action, caused his death, as a temperature of 103° or 105.4° F. would not be fatal. Moreover, the idea so often expressed that a temperature of 113° F. is necessarily and surely fatal is disproved by a patient in the Presbyterian Hospital, whose temperature rose to 115° F., and yet he recovered. That disease is produced when the normal glandular functions cease, or when abnormal

¹ Wood, *loc. cit.*

substances are produced, is self-evident, as is seen in myxedema, exophthalmic goiter, and tetany. If the excretory functions are also disturbed, as in nephritis, uremia, with its convulsions, is an everyday occurrence. Liebermeister's theory that the degenerations seen in fevers with high temperatures are caused by the temperature has long been given up, and it is now believed that the degenerations and temperatures are concomitant effects of the same cause.

Blood changes and petechial rashes, spoken of in the earlier part of this paper, as observed in the hyperpyrexial cases, were also present in the asphyxial form; that is, in patients whose temperature would not account for such changes. The blood-serum from the blood of some patients, when injected in only nine cubic centimeter doses, caused death in rabbits within an hour. I am convinced from my own experiments that normal human serum in such doses will not produce such effects. The urine of patients on admission was found to be markedly less toxic to animals than the urine of the same patients twenty-four to forty hours later, seeming to show a retention of toxic substances in the body at the time of the sunstroke. These experiments, however, are few in number and as yet not sufficiently controlled, but they are very striking.

The theory of auto-intoxication, with heat as a contributing cause, seems, therefore, to be as capable of explaining the symptoms of sunstroke and its sequelæ as the theory that heat alone is the cause. While my own experience last summer inclined me to think that there was something besides the effects of heat which was causing such terrible effects, there is still so much work to be done in the cellular pathology of all the viscera, and so many experiments to be made as to the effects of heat on the animal organism, and these effects studied by the new staining methods in vogue in cellular pathology, that it cannot be claimed that the auto-intoxication theory is as yet conclusively proved. Heat alone, however, does not seem sufficient to explain all the clinical and pathologic observations, while heat with the auto-intoxication of the body better explains the cause and effects of sunstroke.

Koch's New Tuberculin. — In M. Nocard's report on Koch's new tuberculin to the Paris Medical Academy, the Commission of Serums makes an exception in favor of the tuberculin on account of the scientific reputation of M. Koch and the impatience of sufferers to benefit by the proposed cure, and advises the Academy to permit its temporary use. If the usual custom of the Academy were followed the new tuberculin would not be accepted until clinical proof, or at least experiments, proved the assertions made in its behalf.

THE SURGICAL TREATMENT OF GRANULAR CONJUNCTIVITIS.

By J. A. BACH, M.D.,

OF MILWAUKEE, WIS.;

PROFESSOR OF DISEASES OF THE EYE AND EAR, WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.

THE important feature in all forms of treatment of granulations of the eyelids, whether surgical or otherwise, is to remove pathologic elements and to prevent further invasion of the same with their destructive consequences, with the least possible harm to the conjunctiva and lids. Without proper treatment we know that granulations will in many cases ruin eyes, and in others cause serious lesions, either by inducing ulcerative processes or, in the more favorable cases, by producing cicatricial contractions and deformities of the lids. In fact, a large percentage of these patients when they come for treatment have already suffered in same way or other from changes in the mobility or form of the eyelids. These complications, by the additional irritation they induce, further aggravate the unpleasant symptoms and not infrequently produce spasmodic contractions of the muscles of the lids, forming a serious obstacle to the successful treatment of the case. Therefore, often one of the first considerations in the surgical treatment is to remove such complications by proper operative measures. A canthotomy, in cases where this is indicated, on account of the powerful contractions of the orbicularis muscles, will give us the most valuable aid as a preliminary step to further treatment. Other abnormal conditions of mobility or shape of the lids can frequently be corrected with great advantage before proceeding far with the treatment proper.

The surgical treatment, to be of any advantage in the cure of granulated eyelids, must be of a conservative nature and must seek, as far as possible, to *protect* rather than *destroy* invaded portions of the conjunctiva and deeper tissues. We must, therefore, place as foremost of all surgical measures, the expression rather than excision of the pathologic elements in all cases where this can be done. By this means we may not completely succeed in removing all the granulations, but we will succeed in suitable cases if the operation is thoroughly done, as it ought to be, in removing most of them and at the same time in so stimulating absorption and physiologic tissue changes as to lead to a rapid cure of the condition, whether supplemented by further local applications or not. It is not to be forgotten that the ordinary remedies are applied, not with the idea of directly destroying the granulations but for the purpose of inducing that state of local hyperemia which most favors absorption, so that if we can by expression directly remove these deposits we gain valuable

time besides producing the same results physiologically that topical applications produce. Expression of granulations can be employed in all cases but is more especially adapted to the first stages of the disease before the deeper tissues are much involved. When severe inflammatory symptoms usher in the disease it is well to allay such inflammations before applying surgical measures of any kind.

A number of instruments have been devised for the purpose of expression, the most suitable of which are Knapp's roller forceps and Noyes' forceps. Another instrument which may be used with great advantage is the ordinary Desmearre's entropion lid forceps, which in many cases I prefer to other means. However, it is not the particular instrument which one may use in this operation, but it is the completeness with which the operation is done that cures the patient. Frequently expression can be successfully carried out by the use of the finger-nails. Friction, as applied by means of a brush or similar means sufficiently strong to tear the superficial capillaries and soft friable granular masses, without destroying the normal tissue fibers, has been extensively used in some quarters with great satisfaction. Grattage, or scratching by means of a stiff brush or a small metal rake, is a similar means but rather more severe, and ought to be used with care and discrimination. In the first stages of the disease it might do considerable harm by tearing and lacerating the conjunctiva, and, therefore, it is applicable only where there are exuberant and fleshy granulations covering the whole lids, rendering the conjunctiva so completely infiltrated and covered as not to be recognizable. Expression in such cases is frequently not sufficient, as we have here to deal largely with hyperplasia of tissue elements. The results obtained by friction or grattage, by tearing the superficial capillaries, as well as the softer pathologic elements, will cause local depletion and will greatly improve circulation and absorption. It is surprising how quickly thick, fleshy lids can be reduced in a few days by this means where it would take months by means of the ordinary topical stimulation. The good results of this procedure can be augmented by the additional use of antiseptics and astringents. In the more advanced stages of the disease, when deep deposits have taken place, especially at and in the fold of transmission, the venous circulation often becomes very sluggish owing to mechanic obstruction. Absorption under such circumstances is deficient and practically at a standstill. Neither expression nor grattage is fully capable of removing this condition of affairs. Thorough massage has produced good results, although this is not always sufficient. Through the thickening and stretching produced the conjunctiva be-

comes redundant, and the careful excision of the fold of transmission has been practised in such cases with decidedly satisfactory results.

A twofold indication is met in this way: In the first place we remove a large amount of infiltrated and objectionable tissue, and in the second, we destroy the overdilated and inactive blood-vessels and improve the local circulation and nutrition. It has been held that by means of excision of the fold, disagreeable contractions are liable to occur. This, however, is not the case if the excision is done in proper cases and correctly executed. It is desirable to excise as little as possible of the conjunctiva, and as this membrane is quite redundant in these cases no harm can come from this. The main object is to excise the subconjunctival tissue deep in the fold.

Galezowski is an ardent advocate of excision of the fold of transmission and does this as a routine practice in all advanced cases. In his experience he has had no unpleasant results following the operation. Special instruments have been devised for the purpose of excision, among which may be mentioned Galezowski's forceps.

Cauterization by the actual cautery has been practised to a limited extent and, in my opinion, cannot be considered a rational measure. It certainly offers no advantages over excision or grattage, besides being much more liable to leave hard and irregular cicatrices. The principle of electrolysis, which has been practised by different men with good results, would seem more conservative and therefore more applicable. I have had no experience with this method, nor do I believe that it can be made to answer the purpose as well as other means at our command. The operation of scarification of flabby granulations is, in my opinion, objectionable, as by its use we will necessarily sever and greatly injure the conjunctival covering without offering any advantage which cannot better be achieved by grattage. The use of massage, although not strictly a surgical measure, is one of great advantage in conjunction with the various other procedures. In cases in which the disease has run its course and has left behind large atrophic areas of the conjunctiva, or in which this has occurred through severe caustic or surgical treatment, transplantation of the conjunctiva of a rabbit to cover these defects might suggest itself. By thoroughly removing the overlying tissues it would appear simple enough to transplant healthy conjunctiva and give the globe a more acceptable protection.

Legacy for the Academy of Medicine of Paris.—The Academy of Medicine of Paris has received a legacy of 15,000 francs from Mme. Clarens for the foundation of an annual prize.

SKIAGRAPHIC DERMATITIS.

By J. Y. DALE, M.D.,
OF LEMONT, PA.

A CASE of dermatitis presenting unusual features, which occurred subsequent to and was apparently caused by the use of an apparatus employed in taking skiagraphs, recently came under my observation.

On the 12th of last May Mr. T. was subjected, for experimental purposes, to the action of an X-ray tube working at a moderately high power. The tube was applied over the right portion of the umbilical region, unusually close to the body, being not more than two or three inches distant, and the exposure lasted about thirty minutes. No sensation whatever was experienced at the time, nor were there any unpleasant or unusual effects noticed for a period of twenty-eight days, when a scattered eruption of small, round, inflamed and slightly elevated papules made its appearance, and during two or three days these papules increased in number until the redness surrounding them coalesced into a continuous area of inflammation.

When the patient was first seen by me, June 17, 1897, there was an area of inflamed skin of an irregular oval shape about six inches long by four inches wide to the right of and including the umbilicus. It was swollen, purple in color, unhealthy in appearance, and the central portion, which was denuded of epidermis, discharged a creamy pus and contained several spots about an eighth of an inch in diameter where the true skin was eroded to perhaps half of its depth. The inflamed skin was entirely free from pain, and remained so throughout the whole course of the trouble, and there was only a slight tenderness on deep pressure. For three days, during the height of the inflammation, the central portion of the surface involved, which included the ulcerations, was thickened and noticeably elevated, and at that time there was a tendency to coldness of the extremities and general chilliness. These were the only constitutional symptoms which developed at any time. Under the use of mild antiseptic dressings the discharge ceased and the inflammation gradually subsided.

The points of especial interest in this case were the anesthesia of the affected skin, and the length of time that elapsed before the inflammatory process was apparent on the external surface. As there is no other way to account for this attack of dermatitis it is reasonable to believe that it resulted from exposure to the influence of the X-ray tube. This must have injured the sensory-nerve terminals, producing a localized anesthesia, so that the electrolysis of the deeper portion of the skin was followed by a

slow inflammatory process which escaped observation until the papular eruption showed itself.

It seems to be a common opinion among medical men that the dermatitis occasionally following the application of the X-rays is due to some irritating or poisonous property of the rays themselves, but this view is not generally held by electricians and physicists. In an article on the subject by Tesla in the *Electrical Review* of May 5, 1897, he suggests four possible causes of injury during exposure to an X-ray apparatus in action: (1) Ozone, which is produced in more or less abundance, and which has considerable power of destroying organic tissues. (2) Some kind of electric action resulting from rapid and innumerable changes in the electrostatic condition of the tube. (3) Heat (?). (4) The bombardment by innumerable infinitesimal particles hurled against the surface with almost infinite velocity. He is inclined to think that the lesion is the result of either the first or of the second of the above causes. He expressly states his belief that the last is the most satisfactory theory of the physics of the X-ray.

An evidence that the dermatitis in the case reported was not directly due to the X-rays is that the portion of skin which was injured most deeply was directly beneath a broad metallic fastener in the waistband of this gentleman's trousers, which would have arrested the X-rays, but which made a good conductor for electricity.

Mr. I. T. Osmond, Professor of Physics at the State College of Pennsylvania, has explained to me the harmful action of the X-ray tubes in this way: In considering what is the actual agent of injury it is necessary to remember that an X-ray tube in operation is a source of *several different forms of energy*. (a) There is an electrostatic field of rapidly alternating high potential currents emanating from or maintained by it. (b) There is the form of energy known as the cathode rays. (c) There is the form known as X-ray, so called because its real nature is not yet understood, and which may be electromagnetic. (d) There may be the energy of minute particles moving with incalculable speed. Tesla is of the opinion that under the action of the cathode rays there is a disintegration of the reflector plate, which hurls infinitesimal particles off in direct lines with inconceivable velocity. J. J. Thomson, an eminent English physicist, believes that the atoms of the so-called elements are broken up into the really elementary matter, while the studies of Elihu Thomson, a noted electrician of our own country, have led him independently to a similar view.

The following reasons may be given for believing that the X-ray energy is not the agent of injury: (1)

A rapidly alternating high potential electrostatic action will cause similar, if not identical, injuries, under conditions not productive of the X-ray form of energy. (Tesla.) (2) It is pretty well established that the intensity of X-ray energy is inversely as the square of distance from the source, while the power of the injurious agent does not appear to act according to such a law. For a given tube, excited to a given power, the region within which injury may occur seems to have a quite well-defined boundary, ceasing abruptly very much within the extent of strong X-ray energy. (Tesla.) (3) Tesla finds the liability to injury nearly or quite excluded by covering the exposed skin with a fluid (oil or vaselin) which will exclude the contact of air, while at the same time it is very transparent to the X-rays. (4) Again, Tesla finds that all danger of injury, even within sixteen inches of the extraordinarily highly excited tubes which he uses, is removed by placing a thin screen of sheet or gauze aluminum between the tube and person, the screen being well earthed. This screen does not offer very great obstruction to the X-ray energy, as is shown by the strong fluoroscopic or skiagraphic action beyond the screen. (5) The worst spots in these injuries sometimes are in places which the X-rays could not have reached; as before mentioned, the ulcers in the case reported were on a portion of the skin which, during the exposure, was covered by a metal clasp thick enough to prevent the passage of any X-rays.

So far as a conclusion may be drawn from studies and observations yet reported, it seems probable that the injury is due in some way to the rapidly alternating high potential electrostatic action. The electric discharge from the secondary terminals of an induction coil may be alternating, *i. e.*, in different directions successively, and either may be of equal energy in both directions, or of greater energy in one than in the other; oscillatory, as a special kind of alternating; or all in one direction. Even if this action is strictly alternating (as distinguished from fluctuations of intensity of one character), either the intensities of opposite character, positive and negative, may not be equal, leaving a resultant electrolysis from the currents during the changes of states, or if the intensities are equal, and consequently the currents during opposite changes equal, so that the resultant electrolysis is chemically zero, the physiologic functions of the tissues may be destroyed. On the other hand this rapid and great change of electrical state may kill tissues by some other than electrolytic action.

In regard to the method to be pursued in preventing damage to the skin in using X-rays, it may be stated that tubes worked at low power (small coils

and little voltage on the primary) can only produce injury, if at all, by close and very protracted exposures. Very few persons possess the necessary conditions for using the tubes at the extraordinarily high power employed by Tesla.

For tubes used at what may be called ordinary high power, which are actuated by the larger coils coming into more general use, the following rule should be observed: (1) The tube must never be nearer to the body than twelve inches for an exposure of 10 or 15 minutes; and if the tube is highly excited, it is better to increase the distance even if a longer exposure should be required. (2) Tesla's suggestion of covering the skin with some fluid to exclude the contact of air or ozone, may be found valuable. (3) If the tube is sufficiently excited to work at a distance of 15 or 16 inches from the person, with a well-earthed screen of aluminum gauze intervening, absolute security from injury is obtained.

CLINICAL MEMORANDUM.

A CASE OF RENAL HEMOPHILIA.

By WILLIAM J. ROBINSON, M.D.,
OF NEW YORK.

ALTHOUGH hemophilia was known as a distinct disease as early as the twelfth century, and in spite of the fact that during the last fifty years much has been written about it, notably by Virchow, Nasse, Legg, Grandidier, and Simon, we are still in complete darkness as to its pathology and morbid anatomy. Of the numerous theories which from time to time have been offered in explanation of its cause, the following three have met with the widest acceptance: (1) That it is due to an abnormal fragility of the blood-vessels; (2) to an absence of one of the ferments, which effects the coagulation of the blood; (3) to deficient innervation of the capillaries, with consequent abnormal dilatation. But these theories still are mere hypotheses unsupported by facts. As Grandidier puts it, "hemophilia is the most hereditary of all diseases," and, unfortunately, we know as little regarding its treatment as its etiology. Taking into consideration the rarity of the disease, especially of the renal variety, no apology is needed for reporting the following unique case:

Arthur B., four years old, born in this country of Finnish parents, had been passing blood in his urine for about ten days. The mother had consulted her family physician, and had visited two or three dispensaries, but with no relief, the blood becoming more profuse with each urination. At one dispensary she was advised to have the boy circumcised, he having a long and tight prepuce, but this she did not consent to, thus probably saving the child from what might have proved in his case a fatal operation. When I was called in I found the boy playing on the floor with his little brother. He seemed to be completely exsanguinated; his general appearance was as if he were made out of spermaceti, the skin being smooth and glossy

white. His hair, eyebrows, and eyelashes, resembled those of an albino (his two brothers present the same appearance in every particular). His pulse was thready and 140 per minute, and his temperature was 97.9° F. The boy felt quite well and was not complaining. Only occasionally, on passing a blood-clot, he would cry out with pain. There was no history of traumatism.

A thorough examination failed to reveal anything beyond a tenderness over the region of the left kidney. He passed in my presence a pint and two ounces of dark, bloody urine, and floating in it were two long, thin blood-clots. Upon standing the blood all collected at the bottom of the jar, leaving the supranatant urine quite clear. I injected a pint of hot boric-acid solution into his bladder and the liquid came away perfectly colorless. I gave strict orders not to allow the boy to move from his bed, and prescribed powders of one-tenth of a grain of opium and three grains of gallic-acid, one powder to be taken every three hours. I was positive that the hemorrhage was of renal origin, but was completely in the dark as to its cause. This uncertainty cleared away sooner than I expected. About four hours after I left him he was taken with a severe hemorrhage, and became faint. I was sent for in a hurry, and found him in collapse. I administered, hypodermically, my favorite stimulant combination—digitalis, camphor, and ether—to which he responded nicely, but my surprise was very great to find at the point of the insertion of the needle an obstinate, uncontrollable oozing of blood. Compression with the fingers for about five minutes, as well as the application of tannin, cocain, and Monsel's solution was ineffective in checking the hemorrhage. A pledget of cotton, saturated in a solution of equal parts of antipyrin and tincture of ferric chlorid, secured by a tight bandage, after about forty-five minutes of effort, finally stopped it. I knew then that I had to deal with a case of hemophilia.

I began to make inquiries, and the information obtained corroborated my diagnosis. The mother presented nothing abnormal, except rather profuse menstruation, which always lasted from seven to nine days. Her father had died at the age of thirty-five from pulmonary hemorrhages and epistaxis—from consumption, she said, but the description pointed unmistakably to hemophilia. Her first child was born at the end of the seventh month and died when a few days old from exhaustion, due to a severe hemorrhage from the umbilicus. The mother did not know that she belonged to a bleeder family. I instituted the following treatment: A large ice-bag was kept continuously over the region of the left kidney, one grain of sodium sulphate was given every hour, and a dram of the following mixture every four hours:

R Hydrastinin hydrochlor.	.	gr. iv
Ergotole	.	ss
Tr. opii deodor.	.	ss
Glycerin	.	℥i
Aq. menth. pip.	.	q.s. ad ℥iii.

The diet was confined to milk and vichy and soft boiled eggs. The next day the boy had another slight hemorrhage—and that was the last one. For two or three days afterward the urine was very slightly tinged with

blood. After a few days had passed without a trace of blood appearing in the urine, I began to administer iron (liq. ferri mangan. pepton., a teaspoonful in milk twice daily) and tonics, and the boy made a surprisingly rapid recovery. He is now quite well and has had no recurrence (a year has elapsed since his first attack). He is still taking (interruptedly) sodium sulphate, hydrastis, and ergot, and also a preparation of iron. He now has considerable color in his cheeks.

The only other case of renal hemophilia which has ever come under my notice was in Professor Leyden's clinic, at the Charité, Berlin. A man was brought into the hospital in a condition of shock. After regaining consciousness, he said that he was taken with a sudden pain in the side, and on going into a public toilet room, he passed what he thought must have been two liters of blood from the bladder. In the hospital he passed that same day about 1½ liters (three pints) of dark, bloody urine. He was twenty-six years old, and said that he had such attacks every two or three years. He once had pricked his ear with a needle, and it took two physicians several hours to control the bleeding. A brother of his was taken with a frightful hemorrhage from the rectum during defecation and expired before medical aid could be summoned.

MEDICAL PROGRESS.

Anesthetization of Children.—ROWELL (*Lancet*, May 15, 1897) who has had an extensive experience in administering anesthetics, has found that with children he obtains the best results from the use of the A. C. E. mixture, followed by ether, given by the open method throughout. He begins with a small mask, and with the patient lying on the side. The A. C. E. mixture is dropped slowly upon the mask so that it takes one minute for the whole surface to become wet. When respiration has become fairly free, Rendle's mask, containing a sponge, upon which one-half to two drams of the A. C. E. mixture has just been poured, is quickly substituted for the open mask. As the vapor from this mask is stronger than that which the child obtained before, there may be a little straining or coughing. This is relieved by lifting the mask slightly from the face. When the breathing is again free, from one to three drams of ether is poured upon the sponge, and when the child has become accustomed to this, a fresh, dry sponge, upon which from two to four drams of pure ether has been poured, is substituted for the mask. As soon as the child breathes this freely he is ready for operation. The time required altogether is only three or four minutes, and throughout the process the respirations are an accurate guide to the child's condition.

In the case of children who scream and fight, Rowell uses the Rendle mask from the start, holding it close to the face. As soon as the child has ceased crying, the mask must be removed and two or three breaths of pure air allowed. The occurrence of lung trouble, after the administration of ether in children, is almost absolutely preventable by keeping the child in a thoroughly warm room for some hours after the operation. In an experience with nearly 800 cases, in which the anesthetic was

administered by the method above described, no dangerous symptom was observed. Occasionally the symptoms of an over-dose were present, but with proper attention to the patient, even these should never occur.

To Determine the Death of the Fetus.—KNAPP has shown that the death of the fetus, is accompanied by the appearance of acetone in the urine of the mother. This may easily be demonstrated according to *La Presse Med.*, May 22, 1897, by the fuchsin test of Chautard. A solution of fuchsin, 1 to 2000, is decolorized by sulphuric acid. To make the test, half an ounce of urine is poured into a test tube, and a few drops of the fuchsin solution added. If acetone is present, the color of the urine becomes violet, the depth of color depending on the amount of acetone. This simple test is within the reach of every practitioner.

The Hand as a Tampon and Dilator in Placenta Previa.—MYERS, in the *Medical and Surgical Reporter* of May 15, 1897, has found the hand a most successful tampon in cases of placenta previa. If well oiled, it can be introduced without an anesthetic into the vagina, and one finger after another can be passed into the cervix until its dilation is complete, but once in position, the hand must be kept there until labor is terminated, even though some hours intervene.

THERAPEUTIC NOTES.

Erysipelas Treated by Guaiacol.—WAGON (*Gazette Heb. de Med. et de Chir.*, May 23, 1897) has had excellent results from the use of guaiacol in erysipelas. From fifteen to thirty minims of the drug are painted on the affected surface once or twice a day. The temperature falls sometimes as much as four degrees in two hours, the remissions being more striking toward the end of the malady. The fever curve ascends two to four hours later, but there is evidently a permanent as well as temporary effect of the guaiacol.

Aside from its action on the temperature, guaiacol improves the general condition of the patient. The delirium disappears, and the headache, anorexia, and coated tongue, all show changes for the better. Pain is lessened, and restlessness improves with the improvement in the patient's other symptoms. If the drop in the temperature is too great, there is a sensation of great cold accompanied by pallor, profuse sweating, and weak pulse. In the fever which follows this too great depression of the temperature, the patient may expire; but if the dose does not exceed that indicated, the danger of such an unfortunate result is a slight one. Nevertheless, it is beyond dispute that guaiacol is a most powerful remedy, and one which demands on the part of the physician employing it a corresponding degree of watchfulness and caution.

The Therapeutic Value of Ozone.—GESSLER (*Weiner. Med. Blät.*, May 20, 1897) has found the inhalation of ozonized air to have a powerful therapeutic influence. He used an apparatus made by Labbé and Oudin, which was arranged so that each liter (quart) of air contained about

0.10 mg. of ozone. The patients took these inhalations in daily doses, increasing from five minutes to half an hour.

The cases in which this treatment has been used are: (1) In primary and secondary anemia of the severe type; (2) in diabetes mellitus; (3) in tuberculosis of the lungs in different stages; (4) in old cases of pleuritis with adhesions. The best results were obtained in the cases of anemia and phthisis. Of the latter, eight cases, in which the lesion was not pronounced, were much improved by the inhalation. Of twenty-two patients in moderate and advanced stages of the disease, nine died; three were improved so that they might be pronounced cured. Of the remaining thirteen, two were well after 1½ years, and the rest experienced a certain amount of improvement. Examinations for bacilli were regularly made, and it was found that the ozone has an antibacterial action as well as a favorable one upon blood formation. As the effect of the ozone, however, is only temporary, patients ought to receive this treatment continuously. Naturally, dietetic and hygienic measures are also to be instituted.

Tincture of Benzoin for the Itch.—DE HOLSTEIN recommends in cases of itch, friction of the affected parts with tincture of benzoin. In two cases in which it was used the eruption began to subside after the first application, and two days later the patients took baths and were cured. It is possible that the alcohol contained in the tincture deserves a part of the credit for the result, for it could act not only directly but also by opening the crevices in the skin, thus facilitating the entrance of the benzoin into the burrows of the itch insects.

Aseptic Treatment of Burns.—LUTAUD (*Jour. de Med. de Paris*, May 23, 1897) rejects most of the old remedies for burns, on the ground that they are not aseptic. He retains the following:

℞ Sweet almond oil	12 parts
Lime water	2 parts
Salol	1 part.

This mixture, however, is not thick enough to allow of its being applied at the end of the treatment when one wishes to produce a drying up of the burned surface, and, besides, the salol is not dissolved. For these reasons he prefers the following:

℞ Carbolyzed glycerin } aa	5 i
Sweet almond oil	
The yolks of fresh eggs	No. 2.

When this mixture is beaten up it makes a sort of mayonnaise of the proper consistency, and is rendered antiseptic by the carbolic acid. Its application does not cause any pain, even upon the most sensitive surfaces; on the contrary it is itself analgesic. With a forceps this salve is applied to the parts where the epithelium has been lost, and upon the burns of the third degree, and then over the whole bismuth powder is scattered. This dressing is left in place for two or three days, and is then renewed. The results have been most satisfactory. In extensive burns of the third degree, Lutaud has been able to obtain in two or three weeks a complete healing, and that without any cicatricial contraction.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor : J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	\$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JULY 24, 1897.

CHRISTIAN SCIENCE.

OUR attention has lately been attracted to the practical bearing of this cult upon the welfare of the community by several sad occurrences. Some of these incidents are known through personal professional attendance, others through an equally personal and intimate non-professional acquaintance. The first case to be observed was that of a middle-aged woman who had led a life of much hardship, who had been an ardent disciple of Christian Science, and who had spent much of her earnings in the support of "the cause." For a year she had shown some mental alienation; had spent hours writing incoherent messages from spirits or equally incoherent letters to relatives in which the dead and the living were referred to without discrimination; had delusions of grandeur, in that she believed herself to be the medium of communication of a spiritual edict of supreme importance; and she finally developed acute mania, a few days before the time when a settlement of business matters would have left her in a position to enjoy life after her protracted struggle, and to be of comfort and assistance to other members of her family.

The second case was that of a woman of culture who, with her husband and sister, became converts to Christian Science. Shortly after visiting a friend who was dying of gastric cancer, and whom she had tried to persuade to discharge her physician and declare herself well, she was herself seized with symptoms of the same malady. After an ineffectual attempt to "throw off the thought of sickness," a healer was summoned. During the first visit of the latter, she had a sharp hematemesis which he declared to be the visible sign of the dismissal of the disease. Finally, after weeks of suffering, friends interfered and secured the attendance of a physician, who did the only thing possible—relieved her of pain.

The third case was that of a middle-aged man whose wife was a prominent "Scientist," and who, on that account, failed to receive prompt medical treatment for a complication of liver and kidney degeneration. It certainly would be unfair to say that his life was sacrificed to Christian Science, but it is an open question whether it might not have been prolonged for several useful years.

The fourth case was that of a woman, herself a Christian Scientist, and under the influence of the wife of the man referred to above, who kept up her household duties until actually overcome by physical weakness. Relatives insisted on calling a physician, who found the patient pulseless, with advanced double pneumonia, and already in *articulo mortis*. The "Scientist," of course, ascribed death to the neighborly interference.

The fifth case was that of a young man who made a gallant and prolonged fight against multiple tuberculosis, under the auspices, in turn, of homeopathy, Christian Science, and a patent medicine said to contain sulphuric acid, and advertised as the insuperable foe of all bacteria. Death finally occurred during the reign of homeopathy, but when the vital powers were so reduced that no means of treatment would have been of avail. Judging from the resistance made to the disease, it seems that proper and continued treatment might have saved his life if he had not been under the control of "Scientists."

These are not as incisive arguments against the cult of Christian Science as the accounts frequently appearing in the daily press of deaths due to acute causes occurring under the responsibility of healers, when the opportunity of medical aid has been refused either

by the patient or his immediate relatives, but they indicate the same tendencies in a stratum of society in which the demands of custom for the pretense at least of medical attendance, can scarcely be resisted to the last. Indeed, the concession of Christian Science to regular professional practice in these cases has only been to avoid the odium of a coroner's investigation and divide the responsibility of death.

Christian Science is one of the most insidious enemies with which legal medicine has to contend. Ordinary laws regulating the practice of medicine can scarcely be construed to apply to those who declare publicly that they are most distinctly not giving medicinal or even medical treatment. With specious claims to literal truthfulness, the Christian Scientists can claim that they are carrying into practice what every member of any Christian sect and of many other religious bodies, accepts as dogmatically correct. It is impossible to require by law the attendance of a regularly qualified medical man on any particular case. In a general way, necessary medical care is required of those responsible for the welfare of the patient, but it is impossible to lay down practicable rules regarding the degree of physical or mental disability which shall make the calling of a physician imperative. Neither is it within the power of the law to prescribe the qualification of any particular physician or of his school of practice. It is manifestly impossible to discriminate against a school of medicine in good legal and ethical standing, or to go within the limits of any school of practice and endorse certain ideas and condemn others.

Christian Science has its roots in that element of society from which all similar fads derive support. Its advocates are persons of considerable social influence, of good moral character—too good to appear compatible with deeds of inhumanity and tendencies toward murder—of leisure for proselyting. Such persons can not be alluded to as ignorant and uneducated, yet we usually find them superficial in knowledge and comparatively untrained in intellect. They are just the ones who can be convinced by sophistry, and who cannot follow a truly logical mind in the exposure of fallacy. In the event of insanity, or of moral obliquity or foolish conduct, such as hardly warrants the thought of restraint, the question naturally occurs to every fair-minded person, how much is Christian Science the cause and

how much the result of mental unbalancing? We believe that no general answer can be given to this question; that each case must be judged by its particular features. We would, however, assert that in the majority of such instances, Christian Science has acted as an exciting cause and has determined the development of actual insanity, or of serious loss of the reasoning power, in persons who would otherwise be merely incapable of the highest logic, or who would appear slightly below par intellectually.

A NEW RESPONSIBILITY FOR THE MEDICAL PROFESSION.

It is now a generally accepted fact that the bicycle as a means of securing necessary exercise has received the endorsement of the medical profession. Not only do the members of the profession recommend it to their patients as a remedial agent, but they have themselves adopted it as a means of recreation and exercise. This fact seems to have appealed powerfully to the laity, and all remonstrances against riding the wheel in cases in which it is contraindicated are met with the all-satisfying argument that the doctors all recommend it, and the insinuation is that he who does not is behind the times.

In creating and sustaining this universal opinion of approval, the medical profession has assumed to a certain degree the moral responsibility of keeping bicycling within healthful limits. The use of the wheel instead of affording a pleasurable, beneficial exercise, is rapidly degenerating into what gives promises of becoming, if not promptly checked, a great physical abuse.

Every new time-saving invention adds additional strain to the nervous system. The motorman on the trolley line, or the gripman on the cable-car, does not require the same amount of muscular power as the driver of a horse-car, but the increased speed and the constant alertness in avoiding accidents engendered thereby require a higher order of talent and a more sensitive nervous system. The bicycle is no exception to this rule. While in cases of neurasthenia it acts as one of the best remedial agents, when properly used, in diverting the strain from the nervous system and affording exercise to the muscles, thereby equalizing the circulation and nutrition, when carried to the extreme of a century run or a twenty-mile race, it brings such a strain upon the nerve-centers as

to place the latter in danger of total wreck. The man who comes out victorious in a twenty-yard dash or a twenty-mile bicycle race is not the man of tremendous muscle, but one who has his nervous apparatus so thoroughly trained that in the one case he can throw all his power into an almost momentary effort, and, in the second, can set his motor machinery at a certain pace and hold it there with the regularity of a clock throughout the requisite time. This abnormal strain upon the nervous system is the dangerous element in the use of the bicycle. No one who witnessed the twenty-mile bicycle race at Manhattan Beach on Saturday last could restrain his admiration for the careful training and wonderful nerve of the victor, who was able to maintain a two-minute pace for twenty miles; but to the careful observer there was steadily growing, with every lap of the course, in the expression of the rider's face, the protruding, glassy eye, the drawn features, the gaping mouth, which indicate an intense strain and has come to be recognized as the "bicycle face." No organism can endure such over-exertion with impunity. A penalty commensurate with the crime must be paid sooner or later. The less fortunate competitor in this race received his warning promptly and retired from the course at the end of the sixth mile with a stitch in his side.

A still greater abuse, because it is indulged in by a greater number of people, is the so-called "century run," and the still later innovation of the "double century," which was recently undertaken by forty-six riders from New York, thirty-five of whom accomplished the two hundred miles in twenty-three hours. Against such suicidal feats, it becomes the duty of the profession to speak with no uncertain voice.

Professional athletes, whose business it is to develop their muscular and nervous systems for extraordinary feats, are not the proper guides for the great mass of bicycle riders. The latter are composed of professional people and the great class of in-door workers of manifold callings. In them the muscles are soft and flabby, the heart unused to prolonged exercise, and the nervous system already tired from close application. To them, when properly used, the bicycle proves an unalloyed blessing. The exercise it affords appeals to a goodly number of muscles and to all the senses. The mind is diverted by

the constantly changing scenes and sights, the delights of comradeship are begotten, and the invigorating sense of the bounding pulse of full animal life and power is experienced. But the exercise should not be carried so far as to interfere with a proper, healthful reaction; and this should be free from all sense of exhaustion.

ECHOES AND NEWS.

New Use for the Roentgen Ray.—It is reported that in France the Röntgen ray is employed to detect smuggled goods upon the persons of suspected individuals.

A Johns Hopkins University Appointment.—The trustees of the Johns Hopkins University have appointed Dr. John M. T. Finney to be associate professor of surgery.

The Association of Military Surgeons.—The eighth annual meeting of the Association of Military Surgeons of the United States will be held in Kansas City, Mo., June 1, 2, and 3, 1898.

A Statue to Pirogof.—A statue to the eminent surgeon Pirogof will be unveiled at Moscow during the meeting of the International Medical Congress. It is the work of the sculptor, Mr. V. R. Sherwood.

Drs. Munde and Da Costa Honored.—Dr. Paul F. Mundé of New York has received the honorary title of LL.D. from Dartmouth College. The honorary degree of LL.D. has been conferred also by Harvard University upon Dr. J. M. Da Costa of Philadelphia.

Autopsy on a Bridge-jumper.—The autopsy made at the Brooklyn morgue upon the body of Keeble, who lost his life in jumping from the Brooklyn Bridge, showed that death was due to drowning. With the exception of three ribs, no bones were broken.

The Hull Biological Laboratories.—The Hull Biological Laboratories of the University of Chicago were formally dedicated on the 2d inst. The address was made by Professor William H. Welch of Johns Hopkins University. The subject was "Biology and Medicine."

A Hospital for the Medical Department of the University of Iowa.—The Board of Regents of the University of the State of Iowa has appropriated nearly \$150,000 for the construction and equipment of a hospital in connection with the Medical Department of the University.

The American Association of Obstetricians and Gynecologists.—The tenth annual meeting of the American Association of Obstetricians and Gynecologists will be held at the Cataract House, Niagara Falls, Tuesday, Wednesday, Thursday, and Friday, August 17, 18, 19, and 20, 1897.

Delegates to the Montreal Meeting.—Dr. Frederick Holme Wiggin of New York City has been appointed by the New York State Medical Association, and Dr. J. Riddle Goffe by the American Gynecological Society as delegates to

British Medical Association meeting at Montreal, August 31 to September 3, 1897.

International Congress at Moscow.—The "Oto-Rhino-Laryngological Society of Moscow" will open an information bureau in the Doctors' Club (Bolshaya Dmitroffka), and in Section XII. during the meetings, for the convenience of members of that section attending the International Medical Congress at Moscow.

The Prince of Wales' Hospital Fund.—A letter in the London *Times* asks for more subscriptions to this fund. The annual subscriptions at present consist of \$100,000, contributed by less than 5000 households, instead of \$562,500 contributed by 225,000 households, as expected. The deficiency is attributed to lack of thought, rather than to lack of means.

Attorneys for State Hospitals.—Last winter a law was passed by the New York State Legislature providing for the appointment of an attorney for every State hospital. Heretofore all legal work has been done by the Attorney-General's department. The Lunacy Commission has lately announced its selection of hospital attorneys, all of whom are to receive a salary of \$1200 per annum.

Railway Fares and the British Medical Association Meeting.—The Canadian Pacific Railway Company will issue first-class return tickets to members of the British Medical Association from Toronto to the Pacific Coast, at a rate varying between \$61.80 and \$70.30, according to the route selected. This is less than a single fare and the tickets are available from July 1st to October 1st.

Scarlet-Fever Germs in Plunder.—News comes from Bloomfield, N. J., that thieves recently entered the yard of a dwelling in Montclair and stole a quantity of clothing and bedding which had been placed there. Fears are entertained lest this may be the means of causing a small epidemic, for the clothing and bedding had been used by a scarlet-fever patient, and were to have been burned.

She Rides a Cycle at Three.—Birmingham, Ala., claims to have the youngest cyclist in the United States in the person of a three-year-old girl. She began to ride when she was only two years and five months old, and in a month rode well. The wheel she rides is just fourteen inches high, and was made especially for her. The child's baby sister is to be taught to ride when she is two years of age. Comment is unnecessary.

Board of Education and Oculists.—The Board of Education of the City of New York has adopted a resolution providing for the employment of oculists to report upon the best colors to be used in painting and decorating school-rooms with reference to their effects on the eyesight of children. Drs. Chas. Stedman Bull, Henry D. Noyes, and Emil Gruning have been selected to act in this capacity.

Dual Mentality.—An unusual case of dual mentality has been reported by Dr. William A. White of the State Insane Asylum at Binghamton, N. Y., the subject being a girl of thirteen suffering from acute hysteria. The patient

was shown at a recent meeting of the Broome County Medical Society, and experiments were made demonstrating the dual condition of the mind and the existence of a sub-conscious state.

Final Decision in the Fayerweather Will Case.—On July 6th the Supreme Court of New York State issued its final decision in the Fayerweather will case. The executors were required to distribute within ten days the three million dollars in question to the twenty colleges to which they were bequeathed. The various hospitals that were hopeful of recognition under the will are, therefore, debarred from all participation in the benefits of this great fortune.

Military Surgeons of New Jersey Meet.—The annual meeting and dinner of the Order of Military Surgeons of New Jersey was held on the 15th inst. at the club house of the New Jersey State Rifle Association. The following officers were elected: President, Major William J. Parker, Fourth regiment; vice-president, Major H. C. H. Herold of Newark; secretary, Major David Strock, Sixth regiment; treasurer, Captain Roy Inglis, Hospital and Ambulance Corps.

Plague in Hawaii.—The report comes from Washington that there is danger of the bubonic plague being introduced into Hawaii from Japan, where the disease has been carried from its latest colonial acquisition, Formosa. The United States has been warned that its assistance will be required to prevent the landing of infected Japanese, if their demand for admission to Honolulu is enforced by a display of arms such as has just been threatened, and special instructions have been cabled the American sanitary officers in Japanese ports.

Practical Results of Koch's Rinderpest Inoculation.—It is stated by the secretary of the Pretoria Agricultural Society that Professor Koch's results are better than they are said to be. In hundreds of cases the method has been carried out successfully, and the failures which have occurred are due to the impossibility of making the ignorant Boer carry out instructions. He does not think, however, that it is possible to stamp out the disease by this method, as it is impossible to inoculate the hundred thousands of cattle belonging to the natives in isolated districts in various parts of the country. Moreover, he says that the disease is carried from farm to farm by the aasvogel, a species of vulture, which feeds upon the carcasses.

Cowardice of Greek Army Doctors.—Dr. S. C. Zavitziano was sent to Constantinople some months ago as a delegate from the United States to the International Sanitary Commission, and subsequently, at the request of the Marine Hospital Service, traveled through Greece to investigate the treatment received by the Greeks who were wounded in the war with Turkey. He declares that the Greek Red Cross has not been of any assistance, and the same is practically true of the sanitary service of the Greek army. To substantiate his charge of cowardice, he says that the hospitals of Larissa and Tirnova, two of the five hospitals for wounded established at the beginning of the war, were abandoned to the Turks by the physicians. The excuse

offered was that the Turkish army had fired on the Red Cross Hospital at Arta.

Photographing the Stomach.—Dr. Edward O. Schaaf of Newark has invented an electric light and camera for photographing the interior of the stomach. The invention is intended to assist in diagnosing obscure ailments, such as cancer of the stomach. He states that two weeks ago he was able to successfully photograph the interior of the stomach in a living person, and obtained a perfect picture of the pyloric mucous membrane. The great difficulty is in properly focusing the membrane. In the experiments upon dogs anesthetics were used, but the pictures obtained were unsatisfactory. The explanation of this lay in the movements of the stomach. The organ ascended and descended with the diaphragm at each expiration and inspiration. This trouble was overcome when the camera was introduced into the human subject, the patient holding his breath during the exposure of the film. No narcotics are required in individuals, there being no pain connected with the operation. Only five to eight-seconds' exposure to the electric light is necessary, and for this length of time a patient can easily suspend respiration.

Diamond Jubilee Honors.—Among the medical men upon whom jubilee honors have been conferred are the presidents of four large institutions. A baronetcy was conferred on Dr. Samuel Wilks, President of the Royal College of Physicians of England, who has long been known as one of the founders of pathology. A baronetcy was also conferred on Sir William MacCormac, President of the Royal College of Surgeons of England, who was knighted in 1881 in recognition of his services as Secretary-General of the International Medical Congress of that year. The honor of knighthood was conferred on Dr. George F. Duffey, President of the Royal College of Physicians in Ireland, in which he now holds the Chair of Pharmacy as well as that of *Materia Medica*. Mr. William Thomson, President of the Royal College of Surgeons in Ireland, was also knighted. He was the first Secretary-General of the Royal Academy of Medicine in Ireland and held office fourteen years. The honor of a baronetcy was conferred on Mr. Thomas Smith, Surgeon-Extraordinary to the Queen, who is senior surgeon to St. Bartholomew's Hospital, with which he has long been connected. Dr. William Gowers, upon whom knighthood was also conferred, is well known as an investigator of the nervous system whose writings are familiar to physicians all over the world. Dr. Felix Semon was knighted also in recognition of his labors in extending the application of a special knowledge of laryngology by physiologic and clinical investigations. Dr. Thorne-Thorne, C.B., was promoted to be a Knight Commander of the Most Honorable Order of the Bath (civil division). He is lecturer on Public Health at St. Bartholomew's Hospital, where he received his medical education. And Dr. W. M. Haffkine was appointed a Companion of the Order of the Indian Empire in recognition of his well-known labors in India for the prevention of cholera and plague by inoculation.

CORRESPONDENCE.

THE WOODBRIDGE TREATMENT OF TYPHOID FEVER.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the abstract of Dr. Upshur's paper in your issue of June 5th ult. these words appear: "The testimonials which had been filed regarding the efficacy of the treatment ('Woodbridge's method') were of no more value than similar testimonials for some 'cancer cure' or 'kidney cure,' and other 'cures' *sui generis*." The testimonials given out by shameless "cancer and kidney" quacks are the endorsements of their ignorant and deluded victims, generally paid for in service or with salve, and are usually wheedled out of them after a short term of treatment, while they imagine themselves improving and are often published after the giver is in his grave. What are the "testimonials" which Dr. Upshur says are of no more value than these? In 1893, after twelve years of experience which had taught me that typhoid fever *could* be aborted, I made the announcement which was in conflict with all recognized teaching, and published the method which, according to the most advanced thought of the best thinkers, was irrational and unscientific, hence my theories were received with sharp criticism, with positive dissent, and sometimes with violent personal abuse. But a few hundred physicians were possessed of sufficient intelligence to realize that no sane man would promulgate ideas which were certain to be bitterly antagonized until he was absolutely sure that his position was impregnable, and they wrote to me for exact and definite instructions and followed them, and they were soon so amazed at the results which were obtained that they began writing to me in most eulogistic terms of their success, sending me clinical charts and reports of cases. At the last meeting of the Ohio State Medical Society, held in this city, I presented a paper of about 150 pages of closely typewritten brief quotations from these laudatory reports, many of which were accompanied by clinical charts of the cases. The reports included every case and every death as far as I knew which had been treated by the method I have advised, or any modification of it, and dealt with 5449 cases treated, with 105 deaths. Since I read that paper, on May 21st, I have received more than two hundred letters reporting 2408 additional cases treated, with 45 deaths. The record now stands, therefore, at 7857 cases of typhoid fever treated, with 150 deaths, a death-rate of 1.90 per cent., and an average duration of illness in the 4935 cases in which it was given of 12.7 days.

The clinical charts or histories show the most careful and painstaking observations, and that every procedure known to science was called into requisition to verify the clinical diagnoses, and that every possible effort was made to exclude errors of this sort and of judgment. They show that hundreds of cases were treated in hospitals and were carefully watched by different physicians, and that the treatment was instituted in hundreds of cases in which the patient recovered after other methods had

failed, and in many after the patients were considered beyond all human help. It is these reports of cases and the expression of these most highly commendatory opinions which have been based upon the bedside experiences of hundreds of physicians, including many men of the highest social and professional standing, that Dr. Upshur stigmatizes as "testimonials of no value, etc.," and compares with the endorsements given to quack salvers.

Dr. Upshur says he has not used this method of treating typhoid fever, which he severely arraigned, "because he regarded his patients as of too much consequence to be subjected to such dangers." That is, he considers them of "too much consequence" to apply a method of treatment which has resulted in saving all but 1.90 per cent. of the 7857 cases in which it has been tried, besides saving their constitutions the strain of protracted and severe illness, but they are not of too much consequence to be subjected to "symptomatic or expectant" treatment, with its death-rate of fifteen to twenty per cent. and its six-weeks' duration of illness, or for him to sanction "small doses" of always deleterious and generally dangerous phanacetin!

Yours truly,

JOHN ELIOT WOODBRIDGE.

CLEVELAND, Ohio, July 9, 1897.

A REPLY TO DR. LEFFINGWELL.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I have read with much interest the letter of Albert Leffingwell, M.D., in which he criticises your editorial of July 3rd on the bill before Congress restricting animal experimentation in the District of Columbia. It is astonishing to me that any man who values his reputation for intelligence, candor, and carefulness of statement, can make the assertions contained in his letter. He pretends that he would view with disfavor any bill destined to prevent all animal experimentation, and yet we find him associating with, assisting and the chief exponent of those whose object and constant effort is to secure the prohibition of such experimentation.

Dr. Leffingwell says of this bill: "I do not believe that if it becomes a law, it will, in the slightest degree impede any form or phase of useful investigation." The president of the Washington Humane Society could devoutly turn his eyes to Heaven and say the same thing, even though he knew the bill would absolutely abolish vivisection, because he holds that *no form or phase of vivisection is of any practical value to science or medicine.*

Let us see if Dr. Leffingwell's assertions concerning the effect of this bill are borne out by an examination of the text of the bill. He says:

"It now permits all phases of inoculation experiments, all tests of drugs, of poisons, or of methods of surgical procedure. Does it? What does this general provision in Sec. 2 mean? "The experiment must be performed with a view to the advancement by new discovery of physiologic knowledge, or of knowledge which will be useful for saving or prolonging life or alleviating suffering." What proportion of the experiments are made

with a view to *new discovery*, and what proportion are made to confirm discoveries already made or to apply them under variable conditions? In my opinion, and I have had nearly twenty-years' experience with this class of experimentation, this one little paragraph would, if strictly construed, cut off nine-tenths of the useful experiments which are made upon animals. Senator Gallinger, who fathers the bill in the Senate, says this paragraph will not bear this limited construction, but if it does not, why was it put in the bill? It is a principle of law that everything in a law was put there for a purpose. As a matter of fact, the paragraph in question is taken literally from the British antivivisection bill. The framers of that bill believed it would have the full effect which its wording implies, and they inserted another paragraph specifically permitting experiments to test former alleged discoveries. Why was that paragraph left out of the bill which Dr. Leffingwell helped to perfect? Is not the British bill sufficiently harassing and destructive to experimental research?

This bill lays down a number of general conditions according to which experiments may be made, and prohibits all other forms of experiments. These conditions are so shrewdly formulated that, while superficially they do not appear very harmful, the practical experimenter can see that there are very few lines of research which could be carried to successful completion without violating some provision of the bill. For instance, we could not carry out ingestion experiments, inspiration experiments, co-habitation experiments, or exposure experiments, with a view of transmitting a contagious disease and determining the conditions under which the contagion is active. The bill in all such cases makes the prohibitory requirement that the animal shall be completely anesthetized during the whole of the experiment. Again, the ridiculous restrictions concerning experiments made upon horses, asses, mules, dogs, and cats would very nearly prohibit experiments upon these animals. That is to say, the wording of the certificate which must be given, to the effect that the experiment "will necessarily be frustrated unless it is performed on one of these animals" and that "no other animal is available for such experiment" would prohibit many such experiments. It might be much more convenient to use one of the animals named, much less expensive, much more conclusive, and yet some other animal might be available. Again, the delay of a week before the certificate becomes available would prohibit more than half of the original investigations such as I have seen made with these animals. Experiments with contagious diseases, at least, are often planned after the material for them is obtained, and they must be performed at once, or the material undergoes decomposition and is lost. Such experiments cannot be foreseen, and consequently the required certificate cannot be given a week in advance. If to this delay is added the time and trouble required to obtain the signatures of three physicians in active practice and of a professor of a duly established reliable medical school, it is seen that there is here again a very serious prohibition. I am writing as a specialist whose studies are for the most part limited to contagious

diseases. The specialists in other lines of research, such as general biology, physiology, and surgery, feel that they will be almost equally affected. Now, if nine-tenths of the experiments on the pathology of infectious diseases are prohibited by confining such investigations to work for *new discovery*; if a part of the remainder are prohibited by stopping ingestion, inspiration, cohabitation, and exposure experiments; still another part by practically preventing experiments on horses, asses, mules, dogs, and cats, what proportion have we left? More than this, no one can tell how many other lines of experiment will be found prohibited when the bill is actually enforced, if such a catastrophe should ever occur.

With the provisions of the bill a matter of record, how can Dr. Leffingwell truthfully assert that the statements in your editorial in regard to preventing and abolishing animal experimentation in the District of Columbia are "wholly without basis of fact?" Has he read the bill? Does he understand the English language? If so, what is his estimate of the readers of THE MEDICAL NEWS?

The cruelties and abuses of vivisection have been exploited to the fullest extent by Dr. Leffingwell and his antivivisectionist friends, but they have shown no good reason why a different standard of cruelty should be applied to the scientists from that which is applied to the rest of mankind. For all time, it has been admitted that it is not cruelty to cause animals pain where the motive justifies the act. We whip horses to make them obey; we castrate cattle, sheep, swine, and fowls, for economic purposes; we saw or cut off the horns of cattle to prevent them injuring each other; we perform painful surgical operations on animals for purely financial considerations, and in each case we allow the courts to decide whether or not the circumstances of the individual case were such as to constitute cruelty. The bill which Dr. Leffingwell advocates provides that an experiment made with the best of motives, for the most sacred purpose, is cruelty unless performed in a certain prescribed manner and under rigid conditions. It leaves no discretion to the courts to decide whether there is or is not malicious cruelty. In other words, it enacts that certain experiments are cruel, and that the scientists who perform them are criminals whether or not the circumstances of the case justify such a finding.

The language quoted from Dr. Gould may or may not have been founded upon good reason. It suggests to my mind the probability that he had just been reading some of the vivid and soul-harrowing antivivisection literature which is now so abundant. But admitting all that he says, shall we permit the foes of all experimentation to sit in judgment upon our experimenters and say that this man has proper "training and method," and that man is working "only in the interest of vanity?" Have not the antivivisectionists abused in the most unqualified terms some of the greatest scientists that have ever lived? Would they not have stopped the work of Pasteur, Koch, and all of their disciples? Is not a great part of their literature devoted to the task of showing that no discoveries of value have been made by experiments upon animals? Have not the men who made

the greatest discoveries in all departments of science been looked upon as vain, visionary, and deluded, until their demonstrations were complete? No one can foretell who among our scientists will make the great discoveries; no one can tell whose method of investigation is right or wrong; no one can say that an experimenter is actuated by vanity alone, and it would be an outrage on personal liberty and disastrous to scientific advancement to permit any one to make discriminations for any such alleged reasons. What would have become of Morse and the electric telegraph if his methods, motives, and the results he expected to accomplish had been put to such a test. Let science be untrammelled; let research be free; punish only for the crimes which are actually committed, and let us not be led into foolish and harmful legislation by the distorted accounts of experiments in European laboratories, or the mere assertion that experiments are made without sufficient reason here. Every scientific man knows that more experiments fail than succeed in all branches of science; who, therefore, but the experimenter can say whether there was or was not justification for any particular experiment that has failed to yield expected results?

It is not my purpose, however, to favor experimentation or demonstrations by persons whose education does not fit them for such work. I am as much opposed as any one can be to demonstrations by vivisection in the common schools, or to any form of malicious cruelty. Any one who reads the literature of the antivivisectionists can easily satisfy himself, however, that their criticisms are for the most part directed against qualified men, physicians, physiologists, biologists, etc., and it is such men that they are trying to reach by this legislation. All others who conduct painful vivisections can be punished under existing laws. Very respectfully,

D. E. SALMON, D.V.M.

OUR VIENNA LETTER.

[From our Special Correspondent.]

A BUST OF BILLROTH FOR THE UNIVERSITY—AUSTRIAN STUDENT "BUMMELS," DUELLING, ETC.—PLACENTA PREVIA TOTALIS CENTRALIS—PREGNANCY IN AN UNDEVELOPED UTERINE HORN SHUT OFF FROM THE CERVICAL CANAL—SURGERY AND HYGIENE IN CONNECTION WITH THE GRÆCO-TURKISH WAR.

VIENNA, July 5, 1897.

A HALF length figure of Billroth has just been set up beneath the arcades of the University. The memorial to the great surgeon finds a fitting place among the effigies of the other great representatives of scientific medicine in Vienna—Van Swieten, Hyrtl, Schuh, Bruecke, Hebra, and Braun. The figure of the grand old man is very lifelike and characteristic, as he is represented in his surgical gown with scalpel in hand. The formal unveiling is not to take place until the busts of certain other noted University professors, as Werner and Endlicher, have been placed in position, when there is to be an elaborate ceremony.

The University arcades have lost some of their time-

honored traditions, and will cease to have the place in student memories which they have possessed time out of mind, in consequence of a recent decision of the University faculty. It has been the custom for students on Saturdays, when very few lectures are given, to assemble beneath the arcades and promenade there with friends. A perfectly innocent pastime, one might well imagine, and one not calculated to draw down the displeasure of the faculty; but the members of the different student societies usually kept by themselves and glared and cracked jokes at the expense of each other, and the result was student riots and student duels. Here, as in Germany, one frequently meets with the little round vari-colored peaked caps of the duelling fraternities, and most student faces bear scars, some of them recent enough. Not so often among the medical students perhaps as among the others are the society badges and caps noticeable, but almost without exception the faces of the medical assistants in the general hospital bear traces of scars, some of them keloid enough in character to suggest the truth of the remark which has been made that irritants are sometimes deliberately applied to such wounds when recent to make the resultant scar more noticeable.

The Saturday promenades at the University being forbidden (student "*bummels*" as they were called) there has been a noticeable restlessness in the student body during the present semester, as if there were pent-up energies seeking a vent somewhere. At first the faculty prohibition of "*bummeling*" was scarcely taken seriously, and there were Saturday demonstrations at the University. These were promptly put down by the University authorities, and the police department was called upon to enforce faculty regulations. Then there were some demonstrations on the streets and in the parks. About this time the Austrian Reichsrath passed a bill making the use of the Bohemian or Cjeckish language legally obligatory in certain parts of the Austrian Empire. This could not fail to be displeasing to the German students at the University and a lot of the pent-up energy found a vent in a series of meetings in which vigorous protests were made against this putting a despised Slav tongue on a level with their beloved German. The protests culminated just before the adjournment of the Reichsrath in a stormy demonstration by a large student body in the Parliament buildings which required police interference.

There is a good deal of carping criticism at times in America of the amount of attention which is devoted, with the approval of University authorities, to athletics. The critics would find much more reasonable grounds for criticism of the methods generally in vogue at European Universities which the rising generation make use of for the expenditure of surplus youthful energy. The healthy, hearty out-door exercise, with ample opportunity afforded for the utmost expansiveness of superabundant vitality is replaced here by the hilarious drinking parties in the cafés and beer-gardens that too often degenerate, notwithstanding proverbial German student capacity for beer, into drunken revels. The healthy, manly competition of the athletic field, and the training which brings with it precious habits of self-restraint, full muscular de-

velopment and invaluable exercise of the faculty of keeping one's temper are represented in university life only by some monotonous in-door exercise, very slightly indulged in, and the brutal and brutalizing practice of duelling, which neither the ridicule of foreigners nor the growing popular disapproval of it have so far been able to eradicate.

Two of the recent finds in the *post-mortem*-room are interesting as indicating the teachings of the Vienna school of pathology on certain points in obstetrics which are sometimes subjects for discussion. The section of a patient who died from placenta previa revealed the fact that the placenta had been adherent at every point around the internal os. On theoretical grounds it is sometimes urged (it is the teaching of at least one French school of obstetrics) that as the placenta must begin its growth at some point lateral to the internal os it will always remain so, and cannot become a central placenta previa. As a matter of observation the *post-mortem* shows that there have been placental adhesions all around the os, and that penetration into the uterine cavity could only be effected by separating placental and uterine tissues.

A case of pregnancy in a rudimentary horn of a bicornute uterus, where the accessory uterine cavity was completely shut off from communication with the cervical canal, was another demonstration of the wonderful motility of the spermatozoa. Here there seems no question but that the fertilizing element found its way up the only Fallopian tube open to it and thence through the general peritoneal cavity to the ovary of the other side. From here the impregnated ovum descended the tube of its own side into the closed cavity of the rudimentary horn. Such cases are not so extremely rare in literature, but the visible demonstration of what seems almost palpably impossible was extremely interesting.

Austria is so thoroughly on a war footing, and military matters always attract so much attention that the recent Græco-Turkish war could not fail to be of interest in medical as well as army circles. There has been considerable dissatisfaction expressed at the surgical and hygienic arrangements of the sanitary corps during and after battles. Modern scientific methods were not applied as effectively as might be expected in accordance with the advances during the past twenty years. A great deal of attention has been devoted to military surgery and hygiene since the Franco-German and Russo-Turkish wars, and it seems too bad that the first European war since then should not have demonstrated the value of the work done. Some complaints were expressed, too, regarding the attitude of the voluntary nursing associations, even the perfect neutrality of the Red Cross not being always above suspicion. Christian (?) feelings were sometimes thought to have lead to the demonstration of preference to take care of fellow Christians and let the Turks shift for themselves. The subject has aroused renewed interest in the section of military surgery at the coming International Congress at Moscow, where some very important questions are to be discussed. Among them being "The Organization of First Help," "What Primary Bandage for Shot-Wounds is Preferable?" "What

Is the Most Suitable Apparatus for the Treatment of Bullet Fractures?" and "How Can a Supply of Healthy Water be Best Supplied for Use on the Battle-field?"

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE WORK OF THE SANITARIUM ASSOCIATION OF PHILADELPHIA — THE PREVALENCE OF "BABY-FARMING" — STATE AID FOR PENNSYLVANIA INSTITUTIONS — VITAL STATISTICS FOR THE WEEK ENDING JULY 17TH.

PHILADELPHIA, July 17, 1897.

SITUATED at Red Bank, on the New Jersey side of the Delaware river, just below the city, are the grounds and buildings of the Sanitarium Association of Philadelphia, a corporation having for its aims the prevention of disease and the alleviation of suffering among the poor children of the community, by giving them a day's outing in a spot where an abundance of shade trees, and an almost constant river breeze are exchanged for the heat of the city streets and the stifling atmosphere of the slum districts which cause such an excessive mortality in young children. The Sanitarium is open each week-day from June to September, and places no restriction on the number or length of the visits made by the poor. Hourly trips are made to the grounds by two steamboats, the property of the Association, which carry on an average of twenty-five hundred children and their caretakers daily. Here, after a short river ride, which is in itself of no small benefit, the alley-bred children and their elders may look forward to a day of recreation and rest, with plenty of good food for the caretakers, and pure, sterilized milk for the little ones. Large bathing pools for both sexes are provided, and a dispensary for the sick ones is maintained.

The plant of the Sanitarium also includes a children's hospital of commodious size and excellent appointments, which has accomplished valuable results in the past in the treatment of the ailments peculiar to early life. Three hundred or more cases are treated in the hospital during each season, with an exceedingly low mortality, considering the class of patients, and their uniformly poor physical condition.

Beginning in a small way in 1877, the work of the Sanitarium Association has grown and developed in accordance with the demands made upon it, until at the present time, after twenty-years' unremitting and inestimably valuable work, it has become a large factor for good among the class of the community for whose benefit it was intended. Nearly 180,000 children were received during the last season at Red Bank, a large percentage of whom otherwise would have been doomed to suffering and death.

The publicity recently given to the methods pursued in her business by a notorious midwife of this city again directs attention to the existence of these cheap lying-in establishments, with their insinuating advertisements in the public press, of "best care for the mother before and after confinement", and of the boarding and "adoption" of infants. In spite of the fact that the proprietresses of these establishments are utterly ignorant of the first prin-

ciples of the act of parturition, that, for an extra consideration, they do not hesitate to so manage that the unhappy infant handed over to their care shall die of starvation, if the parent does not want to be bothered with the care of the child, and that most of them are on a moral level with public abortionists, if, indeed, they do not sometimes dabble in this trade when circumstances are favorable—in spite of such truths as these, and in the pronounced opposition of the medical profession, these women continue to follow their business, and to obtain from the authorities legal certificates allowing them to do so. And they will continue it just as long as a demand exists among certain classes to escape the consequences and shift the responsibilities of maternity, regardless of the fate of their offsprings; and just so long as the sexually indiscreet continue to find in these establishments a refuge in time of trouble, will legal measures and the sentiment of the better class of the community be powerless to prevent the evil.

And so "baby-farming," with the alarming mortality among its innocent victims from that convenient disease "marasmus," continues to flourish in this enlightened era of medical progress, and it bids fair to exist until laws shall have become more than mere written statutes, or until the community shall have experienced a revulsion of morals. But the latter would be a miracle, and miracles do not come to pass at the close of the nineteenth century.

From Harrisburg comes the announcement that appropriations to institutions not fully under the control of the State and to private institutions will not be acted upon finally until ample time has elapsed for a thorough inquiry into their several needs. This simple announcement may be taken to mean that the hospital appropriation bills of this year will be rushed through the legislature with less haste than is the usual custom in dealing with such items, and that many boards of hospital managers through the State are less certain this year than they have been in the past of expanding their institutions on lines limited only by the generosity of the Commonwealth. In this annual scramble for funds many an honest and deserving charity suffers, while the political dexterity of some totally uncalled-for institution secures for it a tidy sum for "improvements."

Already the supply for hospitals far exceeds the demand, and it would be a sound business principle to reduce their number. But business principles and hospital boards are rarely compatible, so we must continue to look for this yearly rush for money by the deserving and undeserving alike, losing sight of the deleterious effect which this fostering of hospitalism must have upon the income of the general practitioner, not to speak of the moral injury many an otherwise truthful hospital manager must sustain in picturing to an impressionable house of legislature the "pressing claims" of his institution.

The number of deaths in Philadelphia for the week ending July 17th was 528, an increase of 22 over those of the preceding week; of the total deaths, 270 occurred in children under five years of age. The principal causes of death were tuberculosis of the lungs (46), diseases of the

heart (16), pneumonia (22), and cholera infantum (112). The returns of contagious diseases for the week were as follows: 73 new cases of diphtheria, with 14 deaths; 59 new cases of scarlet fever, with 4 deaths; 46 new cases of enteric fever, with 5 deaths. The total number of new cases of contagious diseases numbered 10 more than those of last week, with a decrease in the mortality of 18.

TRANSACTIONS OF FOREIGN SOCIETIES.

Paris.

SATISFACTORY RESULTS FROM CALOT'S REDRESSEMENT BRUSQUE—HYPERTROPHY OF THE PROSTATE RELIEVED BY PROLONGED CATHETERIZATION—NEPHROTOMY FOR HYDATID CYSTS OF THE KIDNEY—RECURRENT FRACTURE OF THE PATELLA—CASES OF DEATH FROM BICYCLE RIDING—THE TREATMENT OF MUCOMEMBRANOUS COLITIS.

AT the session of the Academy of Medicine, held June 8th, MONOD acknowledged that *in Potts' disease good results seem to be obtained by forced reduction (redressement brusque)*, but that time will be required before the ultimate value of this operation is known. In certain cases no attempt at reduction should be undertaken. Such are those in which the reduction, if successful, would leave a gap in the vertebræ too great for subsequent consolidation. Thus, in cases in which the deformity has existed for four or five years or more, forcible reduction exposes the patient to the danger of rupture of the meninges, hemorrhage, tuberculous infection, etc. On the other hand, in deformities which have existed only five, seven, or nine months, reduction usually can be made without trouble.

PEAN expressed himself as satisfied with the operation. One young girl who suffered from paraplegia, due to a deformity about two years old, recovered complete use of her limbs after forcible reduction.

VERGER thought that paraplegia is not sufficient indication for this treatment, as the paraplegia of the lower limbs occurring in Potts' disease often disappears spontaneously.

BAZY has treated several *patients suffering from hypertrophy of the prostate and its attendant evils by the introduction of a catheter*, which is left in place for several weeks, the patients being allowed to go about in the meantime. As a result, a marked atrophy of the prostate follows, and the unpleasant symptoms which are due to its increase in volume (retention of urine, cystitis, etc.) disappear.

At the session of the Surgical Society, held June 2d, HOUZEL described two operations performed by himself *for hydatid cysts of the kidney*. The first of these was a nephrectomy, which was carried out with difficulty and was followed by the death of the patient. In the other case a nephrotomy was performed, with satisfactory results, an operation which the speaker believed to be indicated in most similar cases.

PEYROT has removed one kidney for this cause, with a fatal result. Three other patients upon whom nephrotomy was performed recovered.

At the session of June 9th, PEYROT spoke of the *recur-*

rent fracture of the patella, which occurs in certain individuals who presumably have especially fragile bones. He recalled one case occurring in 1880, in a man aged fifty-four. The patella was again broken during 1883, 1887, 1888, and 1889. There existed no less than three lines of fracture in the patella, each being perfectly distinct. In another case, four or five days after the occurrence of the accident, he had sutured the broken bone anteriorly, with excellent result. Nine months later the bone broke again, and upon examination it was found that the suture had parted and a line of fracture was present passing through the fibrous callous. In another and similar case, the silver wire used for suture was broken at the time of refracture. In this case osseous union had taken place throughout the inner two-thirds of the line of fracture. Both of these patients were treated by passing a wire around the patella as a hoop is placed around a cask. The result was satisfactory.

LUCAS-CHAMPIONNIERE has operated fifty times for fracture of the patella, with four deaths—one from chloroform; one from confusion of the kidney, which had been overlooked; one from constant vomiting, the cause of which was not clear; and a fourth from infection, the case being a complicated one. The results in the other cases were most satisfactory. Only two relapsed, due to the fact that the fragments could not be accurately approximated. In no case was there a breaking of the suture such as described by Peyrot. The patients were allowed to go about in from ten to fourteen days.

At the Medical Society of the Hospitals, June 4th, PETIT mentioned *five cases of death occurring either during or immediately after a bicycle ride* and directly attributable to heart disease. Persons suffering from heart trouble ought to abstain altogether from this exercise or to take it with great moderation. The same is true of those of either sex suffering from tuberculosis of the lungs, and from diseases of the genito-urinary apparatus whether in an active stage or recently cured.

Before the Therapeutic Society, June 9th, MATHIEU discussed *the treatment of mucomembranous colitis*, making the following points: (1) One cannot hope to cure mucomembranous enterocolitis until the constipation, which is its dominant symptom, is made to disappear. (2) There usually exists an irritation of the large intestine which produces not only hypersecretion, but often hyperesthesia, as well as spasmodic contraction of certain zones of the colon. (3) This affection appears especially among persons of a neuro-arthritis or neuropathic temperament. (4) It is very common in women affected with visceral displacements or uterine troubles.

In treating the constipation, violent purges and drugs, such as aloes, which congest the rectal mucous membrane, are to be avoided. Hydrastis Canadensis, or hamamelis are of value. Sometimes regulation of the diet and habits of life are alone sufficient, while hydrotherapy, electricity, and massage give good results. Large rectal injections exert a favorable influence upon the mucous hypersecretion.

Among purgatives, castor oil, in doses of one-half or one teaspoonful, taken before breakfast for several suc-

cessive days, holds the first place, but cascara sagrada, with magnesia and bicarbonate of soda, rhubarb, senna, etc., are almost equally good.

Injections play an important part in the treatment, and they are best given by means of a bulb syringe, the object being to dislodge the fecal masses and adherent secretions. Either boiled water or a solution of bichloride of soda, 1 to 5000, salicylate of soda, 1 to 1000, or chlorid of soda, five per cent., may be used. If the stools are dysenteric, irrigation with a solution of nitrate of silver, 1 to 4000, will be found beneficial.

Vienna.

THE TREATMENT OF OBESITY BY THYROIDIN—THE RELATION OF MUSCULAR SPASM TO DISEASES OF INFANCY.

At the session of the Medical Club, held May 26th, HIEBEL described the *results obtained in the treatment of obesity by thyroidin*. The preparation was taken without difficulty, but often the patients experienced shooting pains in the extremities which lasted for twenty or thirty seconds. In only one instance was the ingestion of the medicine followed by a feeling of anxiety, palpitation of the heart, and headache, symptoms which continued for two days after it was discontinued. In general, the patients lost from two to three pounds a week. In the beginning of the treatment this loss was most noticeable upon the neck and chest, later upon the abdomen and upper extremities, and finally upon the lower extremities. In some instances, while a loss was taking place in the lower extremities, there was actually a gain in size in the region of the neck.

At the session of June 2d, ZAPPERT read a paper upon *muscular spasm in connection with diseases of infancy*. These spasms may be the result of intestinal affections, and also of pulmonary diseases or of septic processes starting from the umbilicus. The spasms may present either of two types, as illustrated by the following cases: An infant with congenital syphilis, pneumonia, and intestinal catarrh, held both arms and legs in a cramped position, but active motions were very slight. Passive motions were strongly resisted. The reflexes were marked. In a second case, of pneumonia, in a child aged seven days, there was tetany of the upper extremities, followed in three or four weeks by a relaxed condition and death. Examination of the chord in these cases showed marked degeneration of the anterior horns in the cervical and lumbar regions. In accordance with these facts, Zappert makes three groups of cases: (1) Various diseases of infancy produce changes in the anterior horn without clinical symptoms. (2) In other cases, tetanic symptoms develop. (3) In the third group are placed those cases in which the stage of irritation is followed by one of paralysis.

A New Narcotic Discovered.—The news comes from the City of Mexico that the physicians of the Insane Hospital for Women, in their efforts to discover some safe narcotic which would produce sleep, are using daily a simple remedy prepared from the seed of white zapote. It is said to produce a tranquil sleep.

SOCIETY PROCEEDINGS.

AMERICAN CLIMATOLOGICAL ASSOCIATION, THIRTEENTH ANNUAL MEETING.

Held at Washington, D. C., May 5, 6, and 7, 1897.

THE President, DR. E. FLETCHER INGALS of Chicago delivered an address in which, after some introductory remarks, he considered the antiseptic treatment and limitation of climatic treatment of pulmonary tuberculosis, showing in eight briefly reported cases that betterment sufficient to be commonly termed a cure may be obtained from antiseptic treatment. He believes that, aside from tonic and nutritive agents, antiseptics are the only medicines which have any power in checking the progress of tuberculosis, especially when used nearly to the point of saturation of the system in cases in the earlier stage. He prescribes the oil of cloves, beginning with five drops in capsules, followed by a glass of milk, and repeated from three to five times a day. He prefers the carbonate of creosote to creosote, or to guaiacol or its carbonate.

DR. FREDERICK I. KNIGHT read a paper on

THE CHOICE OF A SUMMER RESIDENCE IN NEW ENGLAND.

He mentioned three kinds of resorts by the sea: the Maine coast and the Beverly shore, the shore south of Cape Cod, the islands; and two in the country: the mountains, and the country not much elevated, but quite far north. After describing the particular features of these various resorts, with special reference to the winds and changes of temperature, he stated that in case all the members of a family are robust and free from individual contraindications it will in general be found best for those who spend most of the year inland to go to some part of the seacoast for the summer, and for those who live on the shore to go inland or to the mountains.

DR. BOWDITCH of Boston spoke of the stimulating effect of the coast, especially the island portion of Maine. He referred to the fogs and maintained that they are often of a dry character. He said that it may at first seem a misnomer to speak of a "dry fog," but anyone who has been in that region will understand the term. The light vapory mist which frequently drives in from the sea has no definite sense of moisture as it strikes the face and in the midst of it the air frequently feels dry. They are in marked contrast to the drenching fogs of the south shore.

DR. CHARLES D. ALTON of Hartford said that in visiting Nantucket some years ago he carried with him the belief that it might be an excellent place for patients with tuberculosis, but he found that among the natives and visitors numerous deaths occurred from that disease. He did not quite understand this until he began to appreciate some of the local features of the island and its meteorologic phenomena, especially the matter of fogs, as compared with the northern coast resorts. This shows how careful one should be to study the minutiae of localities that are approximate. Physicians often send their patients to California, and not being directed to any particular part of that state, they make a choice themselves of a locality and later are often compelled to seek

another spot on account of the unsuitability of the one first selected. Patients are sent into the Adirondacks without any definite directions as to locality, and one sees them living in close, hot hotel rooms where the conditions are most unfavorable.

DR. R. H. BABCOCK of Chicago spoke of the long winters and comparatively short summers met with in Maine, and said that this accounts for the high death-rate from phthisis, the inhabitants necessarily being confined within doors during a greater portion of the cold season.

DR. JOHN MADISON TAYLOR thought the disease less prevalent in Maine than formerly, owing to an improvement in the quality and quantity of food consumed. He considers the climate of Mt. Desert excellent for neurasthenics and melancholics.

DR. D. R. BROWER of Chicago presented a paper on

CLIMATE IN RELATION TO NERVOUS DISEASE.

Regarding neurasthenia, he said that the special and visceral forms of this disease do best, as a rule, in a marine climate. A sea voyage in a slow sailing vessel is often of the greatest service, as is a residence in a favorable marine climate, such as southern Spain, Algiers, the Riviera, or Italy for the winter, and Holland, the coast of England, Ireland, and the coasts of Norway and Sweden for the summer. The cerebral form of neurasthenia, as a rule, improves in an inland climate, and one of the best in the United States is that of Saratoga Springs, New York, especially in the case of those patients who have marked insomnia, constipation, and uricacidemia. The climatic conditions at Saratoga are eminently conducive to sleep. In cerebral neurasthenia, with no marked disorder of the circulatory system, the bracing air and abundant sunshine of the Rocky Mountains is often highly beneficial.

DR. JOHN MADISON TAYLOR then read a paper on

CLIMATE OR ENVIRONMENT AS A FACTOR IN THE REPAIR OF NEURASTHENIA AND MELANCHOLIA,

and was followed by DR. S. E. SOLLY who contributed one, entitled

THE COMPARATIVE MERITS OF RESORTS IN COLORADO, NEW MEXICO, AND ARIZONA.

DR. R. H. BABCOCK of Chicago then read a paper, entitled

A BRIEF CONSIDERATION OF SOME POINTS IN THE MANAGEMENT OF CONSUMPTION.

DR. KARL VON RUCK of Asheville read one on

THE CLINICAL VALUE OF THE CULTURE-PRODUCTS OF THE BACILLUS TUBERCULOSIS IN TUBERCULAR AFFECTIONS.

DR. FISK read one on

DIGESTION *versus* DRUGS IN THE TREATMENT OF PHTHISIS,

and DR. S. A. KNOPF, one on

AERO- AND HYDOTHERAPEUTICS IN THE PREVENTION AND TREATMENT OF PULMONARY TUBERCULOSIS.

REMARKS UPON THE TREATMENT OF TUBERCULOSIS BY THE ANTITUBERCULAR SERUM

was the title of a paper by DR. HINSDALE who reported the effect of the serum in a case of tuberculosis in which there had been hemorrhages, cough, loss of flesh and abundant bacilli. The improvement was marked and the bacilli disappeared. No unfavorable result accompanied the injections, which were given on alternate days in quantities varying from five to forty minims. The patient is still under treatment.

In discussing Dr. Hinsdale's paper DR. E. A. DE SCHWEINITZ of Washington said that a few years ago he undertook the study of the tuberculosis germs and found they contained about thirty or forty per cent. of fats. He then tried to separate the different acids, and discovered that the fats were glycerids, principally of palmitic acid and high and low melting acids. The germs he used had been attenuated purposely by artificial means. About the same time Dr. Trudeau had made experiments with an attenuated germ and noted similar results. Dr. Trudeau also found that the germs so attenuated were no longer capable of producing disease. Dr. de Schweinitz obtained some interesting results by first attenuating the germs and then inoculating guinea pigs with them and subsequently with virulent germs. In some instances complete immunity was produced.

The next idea to be carried out was the preparation of the antituberculous serum. For this purpose he used various animals—rabbits, guinea-pigs, cows, horses, etc., sometimes using attenuated germs and sometimes virulent ones, and at other times, tuberculin. The serum obtained from these animals was used to treat tuberculous guinea-pigs, with fairly satisfactory results. This serum has also been used by Dr. Stubbett of the Liberty, N. Y., Sanitarium, by Dr. Trudeau of Saranac Lake, and by Dr. C. W. Richardson of Washington. All have reported improvement as regards the effect of the serum on the patients.

DR. CHARLES F. GARDNER of Colorado Springs, read an elaborate paper on

THE DANGERS OF TUBERCULAR INFECTION AND THEIR PARTIAL ARREST BY CLIMATIC INFLUENCES.

DR. I. H. HANCE of Lakewood said that he had made a study of the infectiousness of dust, and had met with some rather surprising results. He had examined three rooms which were occupied by a large family, and had obtained ten square inches of dust from the room occupied by the mother, with which he had inoculated some guinea-pigs. Of the four inoculated pigs, three died of tuberculosis and one of an acute infection. He had also examined the dust in the Broadway cable cars, Elevated cars, and the Avenue C, and Houston Street surface cars in New York City. In the cable cars he had found a greater number of germs than in any cars in that city. The test was not a satisfactory one as it was merely a comparison of the number of colonies which grew on gelatin plates after an exposure of five minutes.

Dr. Hance said that he had used at least two hundred guinea-pigs in experimental work and by far the greater

number of these were found to be free from any tuberculous infection after they had been subjected to inoculation; only those were tuberculous in which he had reason to suspect the presence of the tubercle bacilli previous to inoculation.

DR. S. G. BONNEY of Denver read a paper, entitled OBSERVATIONS UPON PULMONARY TUBERCULOSIS IN COLORADO.

The following papers were then read in full or by title: Undeveloped Graves' Disease Simulating Simple Irritable Heart, by Dr. R. G. Curtin of Philadelphia; Turpentine as a Remedial Agent, by Dr. J. B. Walker of Philadelphia; Some of the Vagaries of Croupous Pneumonia, as seen in Central New York, by Dr. H. L. Elsner of Syracuse; Experiences in the Treatment of Diphtheria, by Dr. L. D. Judd of Philadelphia; The Treatment of Gout by Natural Mineral Waters, by Dr. C. G. Ransom of New York; Report on Mineral Springs, by Dr. A. C. Peale of Washington, D. C.; and Sunstroke, by Dr. W. F. R. Phillips of the U. S. Weather Bureau, Washington, D. C.

The Association then adjourned.

REVIEWS.

DISEASES OF INFANCY AND CHILDHOOD. By L. EMMETT HOLT, M.D., Professor of Diseases of Children in the New York Polyclinic, etc., etc. Pp. 1117. New York: D. Appleton & Co., 1897.

IT is seldom that we have experienced so much pleasure in the course of book-reviewing as in the case of this volume by Dr. Holt. The work is a credit to American medical authorship. Perhaps its most prominent characteristic is its intimate blending of wide personal experience with extensive knowledge of, and large use, of pediatric literature. In consequence the reader feels that, in the statements placed before him, he is made acquainted not only with the author's well-grounded views, but with the generally accepted opinion also. Another excellent feature is the clearness of arrangement and of diction, the author writing in a methodical, *ex cathedra* manner and subdividing what he has to say under convenient headings, so that it is an easy matter for the reader to find just what he wants. We note, too, a judicious use of illustrations where they are needed, there being more than two hundred contained in the book.

The apportionment of the pages to the various subjects seems, on the whole, to be very just. In the matter of giving references to medical literature, there is, perhaps, some cause for criticism. The author, it is true, does occasionally refer his reader to a foot-note, but these are infrequent and are not employed with any uniformity. For instance, in writing of "Winckel's Disease," the foot-note gives reference to Winckel's original article, and to the articles of two other writers, but under "Buhl's Disease," on the next page, no references at all are given, even to the original paper by Buhl. We are aware that there exists a great difference of opinion as to the advisability of admitting references to other literature, some

relegating these entirely to monographs and encyclopedias, but our own opinion is distinctly that they interfere in no way with the value of a work as a text-book for students, and that they are of extreme value to physicians who would wish to consult the writer quoted.

Examining the work a little more in detail, we notice among the contents of Part I, a chapter upon the Peculiarities of Disease in Children. Brief remarks of this nature occur in many other pediatric text-books, but we do not know of any work which equals Dr. Holt's in the treatment of the subject. A chapter on Diseases of the New-born is one which we always look at somewhat askance, although nearly every book of this character contains it. As a rule, a heterogeneous lot of subjects is grouped together, many or most of which could better be classified with other affections, but which are placed here merely for the sake of convenience or to avoid the problem of their proper classification. The present author has cut the number down somewhat, and we should be pleased to see it still further reduced. A large number of pages are devoted to "nutrition," including the study of infant-feeding, also to the diseases directly depending upon faulty nutrition. The remarks on feeding are intensely practical, particularly those upon the method of home-modification of milk for the infant's use. In Diseases of the Digestive Tract he has departed to some extent from the nomenclature most commonly employed, but the departure is all in the direction of increased accuracy, and is to be commended. Respiratory Diseases are very fully treated of, particularly pneumonia, which is illustrated by microphotographs and a colored plate. The section on Nervous Diseases is satisfactory, and that on the Specific Infections equally so. In the latter is exemplified the difficulty of classification which the modern study of infection has imposed upon writers. We refer to the fact that tuberculous bronchopneumonia is described here, while ordinary bronchopneumonia, likewise due to the action of germs, in all probability, and so often clinically indistinguishable from the tuberculous form, is placed under Respiratory Diseases. But this awkwardness of classification is one which the times force upon every author and which only time can remove.

The American practitioner who desires to be fully acquainted with what American pediatrics is accomplishing cannot afford to be without this volume.

A HAND-BOOK OF MEDICAL CLIMATOLOGY. By S. EDWIN SOLLY, M.D., M.R.C.S. Philadelphia and New York: Lea Bros. & Co., 1897.

ONLY those who have had occasion to hunt through libraries for literature relating to climatology can appreciate the value of a general work of the kind which Dr. Solly has given us. There has been a very large number of contributions regarding certain health resorts or climates, it is true, but many of these contain but little valuable information, and others are so prejudiced that they are nearly valueless. In any case, to be able to make a satisfactory comparison of the places and climates described requires a vast deal of reading. This, the author has done for us, and we receive the benefit of his

conclusions. He has made a careful study of the subject from the broad plane of medical climatology, treating it as a science in itself.

The volume is divided into three sections. The first deals broadly with the principles of medical climatology, and describes its close connection with physics, meteorology, ethnology, geography, pathology, etc. Earth, air, water, sun, etc., in their influence upon climate are successively discussed. This section also contains interesting remarks on the influence of race and of geographic position upon disease, and a chapter upon the classification of climates. The second section treats of "The Therapeutics of Climate in relation to Disease," each group of diseases being considered in turn. There is no attempt made here to describe individual health resorts and their adaptation to special diseases. Particular attention is justly given to the climatic treatment of phthisis, and there are valuable comparative statistical tables of the results of treatment at different places. The influence of climate upon other respiratory diseases, heart disease and affection of the liver, kidneys, etc., is also considered.

The third section is devoted to a description of special climates and localities. It is here that we have to make our only criticism. Of course, to give a full description of all health resorts would make a volume far too large for practical purposes, and the author has very properly, as he says, "made the effort to present as many new facts as possible about useful but comparatively unknown resorts," and has described very briefly those regarding which the literature is already ample. Yet it seems to us that almost too much space is given to American health resorts at the expense of those in other parts of the world. Although so many of these have already been described by others, yet the reader of this volume may know little, if anything, about them, and may be turning to it for information; in fact, he may not know where else to look. It is, therefore, greatly to be hoped that in a second edition Dr. Solly will elaborate this portion of the book, and will append a list of references to the literature bearing upon the subject in which fuller details may be found than the compass of a single volume allows.

But this criticism is not at all in the line of condemnation; it is merely a suggestion whereby a valuable work may be made still more valuable. Dr. Solly's book is a very distinct addition to medical climatology—a useful book which should be not only in the hands of every physician with whom rests the important decision regarding the destination of a patient about to leave home in search of health, but in the possession of all those also who have the praiseworthy desire to acquaint themselves with the principles of that important subject, Climatology.

SEPTIC CONDITIONS OF THE INFANTILE ALIMENTARY CANAL. By F. W. FORBES ROSS, M.D. Pp. viii, 138. London: The Rebman Publishing Co., 1896.

THIS little book is a step in advance in the understanding and treatment of the diarrhea and constipation met with so frequently in infants and children. The author

regards the whole alimentary canal as an organic unity, not as a series of parts which are independent in function and therapeutic needs. He sees two causes for the ordinary disturbances—one the result of chemic, the other the result of septic changes. The first mentioned he thinks of less importance than, or as preliminary to, the second. Naturally, therefore, he gives most of his attention to these septic conditions.

The task is really one of the greatest difficulty, and should not, as is here the case, be looked at almost wholly from the clinical view-point. Ever since the appearance of Escherich's work on a similar subject we have recognized the great complexity of micro-organic life in the alimentary canal, as well as the extreme diversity of its main and by-products. Dr. Ross has a good working idea of this, but his elaboration of it is hardly final. His book is earnest and hopeful, but merely preliminary.

He is liberal in his use of drugs, and favors the free administration of intestinal antiseptics, practically ignoring the recognized value of gastric and intestinal lavage. His treatment is apt at times to be somewhat complex, and he holds to some methods which many practitioners do not regard so highly. He believes in the use of artificial pepsin and in the futility of hydrochloric acid; he thinks that there is "nothing so important in the successful treatment of these conditions as the rational and moderate use of opium," and advocates the use of boiled milk. On the other hand, he gives good directions for the care of the utensils of feeding and the proper methods of collecting and handling milk. In an appendix he includes a formulary and method of preparing infant foods.

ATLAS DER KLINISCHEN UNTERSUCHUNGSMETHODEN NEBST GRUNDRISS DER KLINISCHEN DIAGNOSTIK. VON DR. CHRISTFRIED JACOB. Munich: J. F. Lehmann, 1897.

THE fifteenth volume of Lehmann's hand atlases is devoted to the methods and elements of clinical diagnosis. It contains 182 illustrations, 68 being lithographed plates. The blood, the urine, and the feces are shown in their various reactions, the colors being very faithfully reproduced. These are followed by plates showing the normal limits of percussion and their modifications in disease. The various diseases of the heart, lungs, liver, and some of the other abdominal organs are ingeniously portrayed, but we doubt their great value as didactic agents. The accompanying text is clear and modern. The book is handsomely made.

INTERNATIONAL CLINICS, A QUARTERLY OF CLINICAL LECTURES. Edited by JUDSON DALAND, M.D.; J. MITCHELL BRUCE, M.D., F.R.C.P., and DAVID W. FINLAY, M.D., F.R.C.P. Vol. I., seventh series. Philadelphia: J. B. Lippincott Co., 1897.

THE present volume corresponds in point of interest and merit to those hitherto published. It contains clinical lectures on therapeutics, medicine, neurology, surgery, gynecology and obstetrics, ophthalmology, laryngology and its allied branches, and dermatology. The contributors are all well-known clinical teachers, and the lectures are, as usual, beautifully illustrated.

ORIGINAL ARTICLES.

SOME OBSERVATIONS UPON THE ANATOMY OF THE KIDNEY.¹

BY GEORGE EMERSON BREWER, M.D.,
OF NEW YORK;

ASSISTANT DEMONSTRATOR OF ANATOMY, COLLEGE OF PHYSICIANS AND SURGEONS; ATTENDING SURGEON TO THE CITY HOSPITAL.

THE paper upon the subject of movable kidney presented at the last meeting of this Association by our President, and the suggestion that the members of the Association should make as many observations as possible upon the frequency, causation, symptomatology, and treatment of this condition, and report the same at the present meeting, led the writer to undertake a series of clinical examinations with a view of obtaining some data regarding the frequency of the various forms of renal displacement. Accordingly, during the winter, all patients in whom an abdominal examination was allowable, whether they presented symptoms suggesting movable kidney or not, were questioned and examined with reference to this point. The plan followed was, first, to practice general abdominal palpation, with the patient lying upon the back with the abdominal muscles relaxed. If nothing was found suggesting a displaced kidney, bimanual palpation was employed in each hypochondriac and lumbar region, by placing three or four fingers of one hand behind in the angle formed by the spine and the twelfth rib, the other hand being placed on the corresponding area on the anteriorabdominal wall. If the kidney was not felt by this method, frequently the patient was turned face downward upon the table and the method of Professor Guyon employed. Only a few patients were examined standing, as the rigidity of the abdominal walls in this position precluded the possibility of satisfactory palpation. If by any of these methods the kidney could be felt with sufficient clearness to enable the examiner to be positive of the fact, without his being able to grasp the organ or move it about, the case was recorded as one of *palpable* kidney. If the kidney could be grasped and moved about, but did not descend low enough to enable the examiner to palpate its upper border, the case was recorded as one of *movable* kidney. If the kidney

could be freely moved about and if its upper border could be distinctly palpated below the ribs, the case was recorded as one of *floating* kidney.

During the progress of these examinations it occurred to the writer that it might be of interest to make a series of observations upon the position of the kidney in the dead subject, and to compare the positively accurate *post-mortem* findings with the probably accurate results of clinical examination. Through the kind permission of Dr. George S. Huntington, Professor of Anatomy at the College of Physicians and Surgeons, an opportunity was afforded for examining the dissecting-room material for this purpose. Upon his suggestion, therefore, accompanying each subject placed in the dissecting-room was a printed notice requesting the student assigned to the work on the abdomen to leave the kidneys undisturbed until their measurements had been taken. After the student had finished his preliminary study of the abdominal cavity, the peritoneum over the upper third of the kidney was incised, and the position of the highest point of the upper border noted, with its relation to the lower ribs. This was found in the great majority of instances to be about three inches from the spinal column, and between the upper border of the eleventh and the lower border of the twelfth rib. Owing to the obliquity of the ribs in this location, the kidney might occupy any position between these two points, and still be in the same horizontal plane of the body.

The method of making the observation was to strip off the parietal peritoneum and to feel with the finger for the highest point of the upper extremity, then to turn the finger downward over the superior border of the organ and to feel for the nearest rib. The highest rib touched by the kidney was recorded. If the kidney was found occupying a position below the twelfth rib, the distance vertically upward from the highest point of its upper border and the lower border of the last rib was noted. During these observations the number and general arrangement of the arteries supplying the kidney, and also the occurrence of any abnormalities in the ureter were noted, and, although perhaps not strictly germane to the subject of movable kidney, the facts observed have been added to this report, as they cannot fail to be of interest to those who are accustomed to deal surgically with kidney diseases.

The total number of cases examined was 351. Of

¹ Read at the Eleventh Annual Meeting of the American Association of Genito-Urinary Surgeons, Held at Washington, D. C., May 4, 5, and 6, 1897.

these, 200 were clinical and 151 *post-mortem* examinations. Of the 200 clinical examinations, 142 were males and 56 females. The total number of displaced kidneys found in the 200 clinical examinations was 11, or 5.5 per cent. Of these, 9 were reported as palpable, 1 as movable, and 1 as floating. In the 142 males displacement of the kidney was found but twice; in both instances it was the right kidney and was recorded as palpable. The percentage, therefore, of displaced kidneys found in the males examined was 1.4 per cent. In the 56 females examined displacement of the kidney was noted in 9 instances, or 17.3 per cent.; of these, 7, or 12 per cent., were recorded as palpable, 1, or 1.7 per cent., as movable, and 1, or 1.7 per cent., as floating, all occurring upon the right side. Of the 11 patients in whom movable kidney was found, only 1 complained of symptoms which could be attributed to the displaced kidney, and that was in the case of a floating kidney occurring in a very hysteric female. In two instances, the patients being females, it was positively asserted by them that movable kidneys existed, but in neither case did the most rigid examination reveal any sign which could by any possibility be interpreted as indicating the existence of such a condition.

Regarding the accuracy of these observations, I can only say that in every case recorded as palpable, movable, or floating kidney I firmly believe that the kidney was felt. That a number of displaced kidneys may have escaped detection is highly probable, as in many instances, owing to rigidity of the abdominal muscles or to an excessive deposit of fat it was utterly impossible to approximate the two examining hands sufficiently to appreciate the presence of an organ the size of the normal kidney, and the only sensation conveyed to my fingers was a purely negative one.

Post-mortem Examinations.—Total number of subjects examined, 151. Of these, 91 were males, 56 females, and in four cases the sex was not recorded. A reference to the table which accompanies this report will show that the upper border of the right kidney was found opposite the eleventh rib in 78 cases, opposite the twelfth rib in 62 cases, one-half inch below the twelfth rib in 1 case, and one inch below the twelfth rib in 8 cases. The right kidney had been removed in 1 case. The upper border of the left kidney was found opposite the tenth rib in 1 case, opposite the eleventh rib in 100 cases, opposite the twelfth rib in 43 cases, one-half inch below the twelfth rib in 2 cases, three-fourths of an inch below the twelfth rib in 1 case, and 1 inch below the twelfth rib in 2 cases. The left kidney was congenitally absent in 1 case.

If we consider all kidneys occupying a position below the free border of the ribs as pathologic, the number of displaced kidneys found upon *post-mortem* examination of 151 subjects was 14, or 9.2 per cent. Ten of these occurred in males and only 4 in female subjects. Of the 10 occurring in males, 6 were found upon the right side and 4 upon the left. Of the 3 found in female subjects, 2 were right and 1 left. In one instance in which the sex was not recorded a displaced kidney was found upon the right side.

None of the displaced kidneys was freely movable at the time of the first examination, a fact which was probably due to the *post-mortem* solidification of the perirenal fat. In three instances only was there evidence of the kidney being freely movable during life. In one of these, the subject being a male, the upper limit of the right kidney was situated one inch below the last rib and the lower limit one inch above the anterior superior spinous process of the ilium. The vessels in this case passed very obliquely downward and upward to the hilum, and were covered by a very loose and somewhat folded layer of parietal peritoneum, resembling a mesonephron. The renal artery in this instance measured four and a half inches from its origin to the entrance of the main branch into the hilum.

The other two examples occurred in female subjects and had to do in each instance with the right kidney. The upper border in each case was found one inch below the last rib. One presented a well developed mesonephron, and the other a markedly curved ureter with a very much relaxed and folded condition of the peritoneum covering the pedicle.

In six instances the lower border of the kidney was found within one inch of a line drawn transversely across the abdomen connecting the two anterior superior spinous processes, and could scarcely have escaped detection during life had an ordinarily careful examination been made. Four of these occurred in males and two in females, four upon the right side and two upon the left. These conditions were all found in four subjects, two males and two females. In the males it existed on both sides; in the females on the right side only.

It will thus be seen that, whereas our clinical examinations furnished results which seem to confirm the generally accepted opinion that movable kidney is found more frequently in women, and in the great majority of cases on the right side, our *post-mortem* observations furnished facts which were at variance with these views, as shown in the following table of comparison:

Subject of Investigation.	Percentages found in 200 Clinical Examinations.	Percentages found in 151 Post-mortem Examinations.
Displaced kidney found in both sexes.....	5.5	9.2
Displaced kidney found in males..	1.4	10.9
Displaced kidney found in females	17.3	5.3
Displaced kidney found on right side	5.5	5.9
Displaced kidney found on left side	0.00	3.2

Although the writer is unable to offer any satisfactory explanation of this discrepancy, it may, in a measure, be accounted for by the following facts: First, that the number of observations contained in this report is far too small to enable one to draw any accurate conclusions from their analysis; second, the fact that the kidney may be found firmly fixed in its normal position after death by no means proves that that kidney was not freely movable during life; third, that the data furnished by our clinical examinations probably were inaccurate.

In conclusion, I desire briefly to call attention to a few additional facts observed during the *post-mortem* examinations which may be of surgical interest. The left kidney was congenitally absent in one instance. This occurred in an Irishman, thirty-six years of age, who in other respects was apparently healthy. There was not a trace of the kidney, ureter, or renal artery on the left side. The right kidney was twice as large as normal; its upper border reached the eleventh rib, its lower border extended well into the iliac fossa, and the organ could easily have been palpated during life, as the subject was thin. Great variation was found in the distribution of the arteries to the kidney, eighty-five kidneys receiving more than a single trunk. Of these, seventy received two arterial trunks from the aorta, twelve received three, two received four, and one received five, three of these being from the aorta, one from the ovarian, and one from the common iliac.

Twenty-eight kidneys received arterial trunks or large branches in locations other than the hilum. Of these, nineteen received a large trunk or branch at the upper pole and six received it at the lower pole, all of which might easily have been torn off during a nephrectomy while delivering the organ through a lumbar incision. Three received large trunks on their anterior surfaces, which might easily have been ruptured in attempting to separate the organ from the parietal peritoneum. The spermatic artery in a single instance was given off from the renal, and unquestionably would have been included in a ligature of the renal pedicle. In two other instances the spermatic artery arose from the aorta above the renal, crossed the pedicle near its middle, and probably would have been included in such a ligature. In

Left “ “ 11th “

one case two large renal arteries arose from the common trunk with the suprarenal and phrenic.

Considerable variation was observed in the arrangement of the renal, suprarenal, and spermatic veins, but nothing of surgical importance. It may be mentioned, however, that in one instance a large venous trunk from the left kidney passed under the aorta to the inferior vena cava.

A surprising number of variations in the ureter were found, which lead easily to difficulties in diagnosis. For instance, in one subject four ureters were found, two from each kidney. The two from the right united near the bladder, while the two from the left entered the bladder separately. In another subject there were two complete ureters, the one emerging from the upper portion of the kidney being

markedly diseased, as was the pelvis of the organ, while the one from the lower segment of the kidney was perfectly healthy. In two other instances double ureters existed above, but united to form a common trunk below. These and a number of other anomalies of minor importance are fully described in the table which accompanies this report.

SUMMARY OF CONDITIONS FOUND UPON POST-MORTEM EXAMINATION.—POSITION:

The upper limit of the right kidney was found opposite the eleventh rib in 78 cases; opposite the twelfth rib in 62 cases; one-half inch below the twelfth rib in 1 case, and one inch below the twelfth rib in 8 cases. The kidney was removed, or position uncertain, in 2 cases. The upper limit of the left kidney was found opposite the tenth rib in 1 case; opposite the eleventh rib in 100 cases; opposite the twelfth rib in 43 cases; one-half inch below the twelfth rib in 2 cases; three-fourths of an inch below the twelfth rib in 1 case, and one inch below the twelfth rib in 2 cases. The left kidney was congenitally absent in 1 case.

ARRANGEMENT OF STRUCTURES AT PEDICLE.

Number of right kidneys supplied by a single renal artery, 112; by two arteries, 33; by three arteries, 5. Number of left kidneys supplied by a single renal artery, 103; by two arteries, 37; by three arteries, 7; by four arteries, 2; by five arteries, 1. Number of right kidneys receiving large arterial trunk or branch at upper pole, 8; at lower pole, 3. Number of left kidneys receiving large arterial trunk or branch at upper pole, 11; at lower, 3. Number of right kidneys receiving large arterial trunk or branch on anterior surface, 2. Number of left kidneys receiving large arterial trunk or branch on anterior surface, 1. Spermatic artery (right) arising from renal, 1. Spermatic artery (right) arising from aorta above renal, crossing pedicle, 2. Widely separated renal arteries (right) crossing between aorta and hilum, 1. Widely separated renal arteries (left) crossing between aorta and hilum, 3. Left renal branch arising from ovarian, 1; arising from common iliac, 1. Two large renal trunks (right) arising from common origin, with phrenic and suprarenal, 1.

URETER.

Double ureter, complete (left), 2. Double ureter to point three-quarters of an inch from bladder (left), 1; to point two inches from bladder (right), 1; to point six inches from hilum (right), 1; to point $1\frac{1}{2}$ inches from hilum (left), 1. Bifurcation of pelvic at hilum (left), 1. Ureter lying anterior to lower accessory renal artery (right), 2; (left) 2. Ureter markedly curved from malposition of kidney (right), 1.

TYMPANITES.¹

BY MILES F. PORTER, M.D.,
OF FORT WAYNE, IND.;

PROFESSOR OF SURGERY AND CLINICAL SURGERY AND OF CLINICAL GYNECOLOGY IN THE FORT WAYNE COLLEGE OF MEDICINE.

I wish in this paper to call attention to tympanites intra-intestina, not as a symptom the principal importance of which lies in its diagnostic significance, but as a condition which is often the immediate cause of death. With hysteric tympanites I shall not concern myself.

Abdominal surgeons perhaps best appreciate the dangers of tympany, but I believe that even many who do a good deal of work in this line underestimate its importance. Many patients with abdominal disease die, in whom recovery would occur if the tympany were relieved. In many cases of peritonitis, for instance, drainage of the bowel is scarcely, if at all, secondary in importance, as a remedial measure, to drainage of the peritoneal cavity. One not infrequently meets with peritonitis accompanied by diarrhea, but one seldom sees death result from peritonitis when the bowels are open. Is not the explanation of this fact to be found in the absence of tympany? Tympany seriously embarrasses the lungs and heart, and, as Fenwick has pointed out², may cause sudden heart failure.

B. E. Hadra of San Antonio, Texas, reports a case of general peritonitis cured by intestinal drainage alone, without drainage of the peritoneal cavity³. Henrotin⁴ ascribes the recovery in two of his cases of peritonitis to the formation of an artificial anus. The writer has operated in a case of intestinal obstruction, with a large abscess extending above the pelvic brim, in which he contented himself with forming an artificial anus, postponing the opening of the abscess and the relief of the obstruction *per se* until the woman's condition improved.⁵ The tympany was immediately relieved, the pulse and respiration improved, the bowels moved *per vias naturales* twenty-four hours after the operation, the abscess discharged spontaneously on the second or third day, and the woman is well, save a small intestinal fistula which should be closed by operation.

Given a case of general purulent peritonitis with marked tympany, I would as soon think of closing the abdomen after celiotomy without drainage of the peritoneum as without opening and emptying the gut. Though tympany is most often seen in connection with disease of the peritoneum or of the abdominal or pelvic viscera, it not infrequently menaces life in

other pathologic conditions. The following are cases in point:

Mrs. K. was taken with chill, after having complained for a couple of weeks of a mild bronchitis, and soon developed the usual symptoms of a bronchopneumonia, with considerable plastic pleurisy.

On the seventh day of the disease tympany began to develop rapidly, the pulse grew irregular, rapid, and feeble, respiration became much more embarrassed, and cyanosis was marked. Repeated rectal injections of water and turpentine finally resulted in the expulsion of gas in large quantities, with a subsidence of the more alarming symptoms; recovery ensued, though resolution was very tardy.

Another case almost identical with that of Mrs. K. occurred in the writer's practice in the person of Miss B., the only difference in the two cases being that in the latter the symptoms did not become so alarming, owing, I think, to the lesson I had learned from the case of Mrs. K. Two similar cases in the writer's practice during the past winter ended fatally.

Mrs. W., a patient of Dr. Carl Schilling, was operated on for fibroid of the uterus by the writer, on February 24, 1897. I performed a complete hysterectomy, without drainage. Tympany and vomiting interrupted the convalescence, though there was no tenderness, suppuration, or other evidences of peritonitis or sepsis. The vomiting stopped, and the pulse and respiration, both of which had grown alarmingly bad, improved immediately upon relief of the tympany. There was complete primary union of the wound, but the stitches were allowed to remain in place until the tenth day, on account of the tympanites.

A case of marked tympany, occurring in the writer's practice in the person of a Mrs. M., on the second day after the birth of her first baby, after a natural labor, without any symptoms of sepsis of any sort, convinced him that a bandage properly applied after labor not only conduces to the woman's comfort, but enhances her chances of a speedy and safe recovery.

There are two causative elements present in most, if not all, cases of severe tympany, *viz.*, obstruction to the passage of the gas, and undue formation of gas. The obstruction may be negative or positive, *i. e.*, due respectively to paresis, or to one of the many well known physical causes of obstruction. In many cases a combination of causes exists. For instance, a band may produce an obstruction of the bowel so slight as to attract no attention until an undue formation of gas makes the obstruction complete. It is such cases as this that are cured by simply opening the bowel and allowing the gas to escape. Paresis of the bowel may either be a cause or an effect of tympany, in the latter case being due to distention. It follows, then, that we have the element of paresis to reckon with in many, if not all, cases of severe tympany that have existed for many

hours. I have opened a distended bowel on more than one occasion only to find that it could not empty itself, and it had literally to be stripped in order to relieve the abdominal distention.

The effect of atropin upon the muscular structure of the bowel should be borne in mind when using this drug, particularly in abdominal cases. In many cases of tympany the distention is practically confined to the large intestine, and, as Sweetnam¹ has pointed out, this is particularly true of tympany coming on after celiotomy, and is due to the "downward pressure of the descending colon and sigmoid flexure upon the upper portion of the rectum, forcing the folds of Houston one upon the other, and bringing about, in this way, what is for the time in effect an impermeable stricture."

The prophylactic treatment of tympany should never be neglected in cases in which it is apt to occur. Thorough evacuation of the bowels by salines, the internal administration of antiseptics such as salol and salicylic acid, a diet of food not prone to fermentation, combined with the judicious administration of strychnin and the use of the abdominal bandage, has in a large degree robbed tympany of its terrors for the abdominal operator. The same means will accomplish the same ends in cases other than those requiring abdominal surgery. The measure of success which shall attend our efforts in the treatment of tympanites will depend very largely upon the time the treatment is commenced. This should be instituted when the condition first manifests itself, for delay is dangerous. The giving of cathartics is worse than useless in the presence of pronounced paresis, and under the same circumstances the rectal tube and enemata will be of little avail. The utility of the latter in some forms of bowel obstruction, together with its inutility and actual harmfulness in some kinds of obstruction, are well known, and need not occupy our time here.

To Sweetnam, to whose papers I have already referred, belongs the credit of priority in recommending the postural treatment of tympany. He had observed that relief could often be secured by elevation of the hips, and was in the habit of employing position in the treatment of this condition, but he says that he did not fully appreciate "the amount of alteration which takes place in the rectal folds when one is placed in the knee-chest position" until, while watching Howard Kelly making a rectal examination, he was able to see the folds of Houston disappear into the rectal wall, and the gut straighten out. The treatment is harmless in all cases, but useless in Sweetnam's experience, in cases of general peritonitis. I am not surprised that he should obtain

no results from this method in general peritonitis, for here the distension is in the small bowel, and it is only in distention of the colon that it could be effective. The knee-chest position is considered best, but the elevation of the foot of the bed, with the patient on the side, will usually be effective in cases of moderate distention. Personally, I have had no experience with this method, but shall certainly try it when the opportunity offers.

Notwithstanding that the statistics collected by Ogle¹ seem to show that puncture of the intestine, multiple if necessary, is fraught with little danger and is usually successful in relieving the distention, it certainly seems unsurgical, to say the least, and should be resorted to only in cases in which opening the abdomen is entirely out of the question. This measure should be employed, however, in my opinion, when death is threatened by tympany, in cases which have resisted milder means and in which celiotomy could not be borne.

I believe that in all cases, whether abdominal or not, in which tympany threatens life, and persists in spite of the usual methods to combat it, the abdomen should be opened and the gut incised and emptied. Exceptions should be made in favor of puncture in cases in which celiotomy would prove fatal. If the patient's condition permits, the incision into the bowel should be closed after the gut is emptied, and the abdominal wound closed. As a rule, of course, one should seek to relieve the cause of the tympany at the same time that the tympany itself is removed, but, as indicated above, this is not always advisable. It will often be found better to leave bowel obstructions, pelvic abscesses, etc., for a future operation, when the patient will be better able to stand the shock. Under such circumstances, the cause of the detention remaining, it will usually be necessary to make an artificial anus instead of closing the bowel and returning it to the abdomen. I wish to say, and I speak from experience, that the operation here advised can be successfully performed in the case of patients who seem almost at Death's door.

I think I am warranted in concluding as follows:

1. That intra-intestinal tympany in and of itself often kills patients suffering from abdominal and pelvic disease, and that it may do so in cases which are neither pelvic nor abdominal.
2. That tympany occurring in the course of any serious illness should be considered a symptom of ill omen, and that measures for its relief should promptly be instituted.
3. Failing to obtain relief by cathartics, posture, enemata, and the use of the rectal tube, celiotomy and incision of the gut should be promptly done.

¹ *Annals of Surgery*, March, 1896.

¹ *MEDICAL NEWS*, February 9, 1899.

4. In cases of general peritonitis and bowel obstruction, no trial should be made of other methods, but celiotomy and incision of the gut should be performed as soon as the diagnosis is made.

5. Puncture of the bowel should be carried out only in cases in which the patient is *in extremis*, and then only in cases such as typhoid fever without perforation, pneumonia, etc., which present no other cause for celiotomy than the tympany itself.

THE NEWER PREPARATIONS OF BISMUTH.

By REYNOLD W. WILCOX, M.D.,
OF NEW YORK;

PROFESSOR OF MEDICINE AND THERAPEUTICS IN THE NEW YORK
POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN
TO ST. MARK'S HOSPITAL.

ABOUT three years ago I published, in the *Post-Graduate*, my investigations upon certain definite chemic compounds of bismuth with phenol, naphthol, and tribromophenol. At that time I summarized my results from the cases of more than one hundred patients who had been treated with these preparations. I believed that a real advance had been made toward attaining intestinal antiseptics.

The use of bismuth internally is too ancient to admit of argument as to its value. The soluble salts have a limited use, for, so far as our knowledge goes, they act similarly to those of mercury. The subcarbonate and subnitrate, in view of recent discoveries, certainly have a limited use. The former, on account of its generation of carbon dioxid gas in certain combinations, could well be dispensed with altogether. The subnitrate has its only special use in the treatment of gastric ulcer, where its high specific gravity gives it a certain advantage, and this is, in my personal practice, its only use and even here I believe that the naphtolate should be administered coincidentally.

Of the three preparations to which my former paper was mainly devoted, I have found that the bismuth naphtolate (bismuth oxid, 80 per cent., and betanaphthol, 20 per cent.) is of the greatest value. This preparation is decidedly antiseptic, if Jasenski's experiments in Nencki's laboratory are trustworthy, and, besides, observation certainly confirms them. It is partly decomposed in the stomach, but the process is completed in the small intestine. The naphthol is partially, a small part I believe, eliminated by the kidneys and a larger portion passes entirely by the bowels. The bismuth is eliminated by the bowel as a sulphid, but the rapid disappearance of odor cannot be entirely due to this chemic combination.

Several observations show that there exists a marked antiseptic action from the use of this preparation. One of the most severe instances of intes-

tinal putrefaction which I have ever encountered occurred in the person of a veteran of the Civil War. This man was wounded by a fragment of shell which carried into the liver portions of clothing, which lodged in that organ. During two years there was continual suppuration, with discharge of foreign matter, before healing was complete. When the patient came under my observation the liver was not palpable, and percussion showed the area of flatness to be diminished to one-sixth its normal degree. In this case the discharge of gas was so continuous, and in such large amounts, that although no sphincteric incompetency existed, one could readily believe that the fecal odor which surrounded the patient was due to that condition. The enormous distention, the secondary results, and the disturbance of nutrition rendered the patient's condition truly deplorable. A faithful administration of the bismuth naphtolate not only relieved the patient of the offensive odor and limited the tympanites, but gave great comfort and improved his nutrition, so that within a month he expressed himself as being completely relieved. This relief has persisted under the administration of the drug for the past two years.

Of the typhoid fever patients who have come under this treatment during the first week or ten days of their illness, none have presented the classic symptoms, and all had a low temperature without marked abdominal symptoms, and without, as a rule, any indication for further medication. Neither diarrhea, fetor, or tympanites occurred. There was no fear of perforating ulcerations, for there is but little opportunity for ulceration in a bowel in which there is no fermentation going on. Obviously, in patients who are markedly septic after expectant tubing, or after no treatment has been instituted, another plan must be pursued. These are instances of bad management, and are septic cases in which all remedies which benefit general septicemia are applicable.

Following Hueppe, bismuth tribromophenolate has been used extensively; its use is similar to that of the naphtolate. Of late, I have not used this preparation as extensively as the naphtolate, although its sweetness and astringency are certainly of advantage. The phenolate has proved its utility in a large number of instances of gastric fermentation. From the use of neither of these drugs have I observed toxic symptoms, and frequently I have administered them to the amount of 90 to 120 grams daily. Their harmlessness can be attributed to the fact that they slowly decompose and the phenol is not set free much faster than it can be eliminated. My observations have been confirmed by Fischer, Engel, Chaumier, and many others, and can be considered accurate and re-

liable. I have but little to add to and nothing to retract from the statements which I made three years ago.

The most important addition to the therapeutic uses of bismuth naphtholate is in the treatment of the diarrheas of patients suffering from pulmonary tuberculosis. It is well known that next to the complication of tuberculous laryngitis, diarrhea is the most unfortunate. Even a few days of profuse discharges will undo the work of weeks. In several instances a rapid increase of the dose of the naphtholate to 60 or even 120 grains daily has given brilliant results; in one patient, however, there was utter failure, and in his case no drug or combination of drugs was of any avail.

During the past year I have employed in the cases of thirty-five patients a drug chemically known as bismuth tetra-iodo-phenol-phtaleinat (endoxin). This is an insoluble, reddish-brown, odorless, tasteless powder, which contains 52.9 per cent. of iodine and 14.5 per cent. of bismuth. It is claimed that it is non-toxic, and it is believed to decompose in the presence of alkalis into bismuth oxide and tetra-iodo-phenol-phtalein; therefore, it should pass through the stomach unchanged, and the last-named drug should be dissolved in the intestinal contents. Since this is soluble, not only will the contents of the bowel be disinfected, but also the intestinal walls, and the drug again be excreted into the intestine. I was induced to experiment with this drug by the following facts: (1) Lieven reports a permanent and energetic antiseptic action on the bacteria of pus and saprophytes; (2) the dose (5 to 8 grains thrice daily) is smaller than of similar preparations; and (3) I believe that the effect of the contained iodine upon the intestinal glands may be a beneficial one. On the other hand, I was prepared to find the lower bismuth percentage a disadvantage, and the possibilities that the contained iodine might prove to be an irritant.

Fourteen of the patients treated with this drug suffered from chronic intestinal catarrh; of these, six presented coincident hepatic and cardiac lesions. Naturally, the latter class would be benefited by drugs which would influence the liver and heart, but I am sure that the benefit was more rapidly obtained than it would have been without the use of the bismuth preparation. Three patients presented intestinal fermentation, with discharges of muco-pus, considerable pain, and foul-smelling stools; these experienced relief, although one required treatment for several months. One patient, who suffered from the above symptoms, was relieved as far as fetid stools and mucous discharges were concerned, but the pain and distention persisted. In this instance there was no reason to suspect malignant disease, and doubtless intestinal adhesions were the cause of the permanent

disability. Four patients suffered from simple intestinal fermentation. These were permanently relieved, although in one instance nearly five months elapsed before treatment could be suspended. Two patients, both women, suffered from exfoliative membranous enteritis; both were put to bed and received high intestinal irrigation with salol, with a carefully arranged diet and general supervision of all matters which were conducive to restoration of health. In addition, the drug was used in maximum doses. Both patients have now passed some months (one, three, the other, two) without the passage of shreds or membranes.

Nine patients presented symptoms of both gastric and intestinal catarrh. They all improved, but not so rapidly as could have been wished until resorcin in 5-grain doses was given before meals. The final result was satisfactory. One patient, markedly lithemic, was partially incapacitated by the extreme fermentation which followed his two principal meals. In addition to the intestinal symptoms, there was excessive irritability of temper and fits of unaccountable melancholy. The drug, even with careful attention to hygiene, failed, while excessive amounts of chlorin water (U. S. P.) succeeded in causing a cessation of fermentation. Acute dysentery, tenesmus, blood-streaked stools, fever, and hepatic tenderness were relieved within ten days. But little can be said of this patient; the cause and variety of his complaint was not well studied. Recent cases have been far more amenable to treatment.

No opportunity had been offered for the use of the drug in the long-standing chronic fevers, which are the really difficult ones for establishing intestinal antiseptics, until finally two patients presented themselves suffering from acute catarrhal duodenitis, with cutaneous itching, absorption jaundice, tender liver, and clay-colored and offensive stools. Both were relieved, so far as their intestinal symptoms were concerned, although calomel in small doses (gr. $\frac{1}{10}$) at hourly intervals was given. Both presented well-marked conditions, and, I am sure, obtained relief from the intestinal decomposition with more than usual rapidity. I have met with no distinctively toxic symptoms. However, one of the women who suffered from chronic membranous enteritis developed an iodine-acne which, although not severe, prejudiced her so much against the drug that she would not admit the benefits which it was evident that she derived from its use. The drug was not irritant in the patients under observation, although I believe that the effect of the iodine content of the drug upon the glands of the intestine is to render the stools less consistent. I have had no experience with the remedy in either the diarrhea of the tuberculous or in typhoid fever.

The drug was generally administered as a powder, diluted with equal parts of milk sugar; very rarely was it given as a compressed tablet.

From this brief survey of the results of the administration of the newer bismuth preparations, we may conclude:

1. That the use of the organic in place of the inorganic bismuth compounds should be insisted upon.
2. That the compounds of bismuth with betanaphthol, phenol, tribromophenol, and tetra-iodophenol-phtalein are remedies which produce practical intestinal antiseptics.
3. That they are indicated in all gastro-intestinal fermentations and catarrhs until the symptoms are relieved, the dose to be determined by the severity of the symptoms.
4. That they are non-toxic and do not give rise to untoward symptoms.

CLINICAL MEMORANDA.

A CASE OF PULSATING PLEURISY.

By J. N. HALL, M.D.,
OF DENVER, COL.;

PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE IN THE
UNIVERSITY OF COLORADO.

W. C., male, five and one-half years of age, of tuberculous parentage, was first seen by me on December 31, 1895, at which time he complained of pain in the left side, cough, and dyspnea. Upon examination, I found him to be very anemic, and the whole left side of the chest was flat, with the exception of an area of Skoda's resonance at the apex. The usual signs of effusion were present, the apex beat being two inches to the right of the sternum. The whispered voice was heard over the entire left chest. A diagnosis of serous effusion was made, and on the following day Dr. O. J. Pfeiffer aspirated and withdrew thirty ounces of serum. The heart returned to its place, and the dyspnea was wholly relieved. The child improved steadily, although moderate dulness reappeared in the lower part of the chest, posteriorly. As he was eating well and gaining in weight, he was dismissed during February, the dulness having nearly disappeared and the general health being almost restored.

On March 7th I was sent for in haste, the mother stating that "the child's whole left side was beating." She informed me that the boy had been feverish during several days and had not felt as well as before. I found his temperature to be 102.8° F., and his pulse 144 to the minute. The apex beat was one and one-half inches to the right of its normal position, the cardiac dulness corresponding. The left side of the chest was flat upon percussion, as before, except that the dulness was less extensive. The whole lower left chest, to the posterior axillary line, pulsated synchronously with the heart, this being noticed both by inspection and palpation. Slight edema existed over most of the pulsating area. There was no bronchophony, as in the case of the former effusion.

The child was immediately removed to St. Luke's Hospital, and the following morning, after verifying the presence of pus by aspiration with a hypodermic syringe, was operated upon by Dr. Pfeiffer, the usual permanent opening and drainage being employed. It was estimated that twenty ounces of pus were evacuated. No gas escaped from the pleural cavity, and the pus resembled in gross appearance that of an ordinary empyema. The child made a slow but uneventful recovery. The heart is now displaced slightly to the left of the nipple line, as a result of contraction of the left lung following its compression. I have no doubt that this result could have been avoided had the child's relapse been promptly reported to me.

It should be further stated that at the time of operation the pulsation, much to my surprise, had nearly disappeared. I have since noted that it has been recorded in several cases that the pulsation was present only when the patient was placed in certain positions, being absent especially in the recumbent posture in several.¹ In this case the first examination was made while the child sat in its mother's lap, and the second, after the child was stripped and laid upon the operating-table. It has occurred to me, also, that possibly the less forcible cardiac action, at a time when the temperature is commonly lowest, may have entered as a factor into the case, since the first examination was made in the late afternoon and the second in the early forenoon.

No sufficient explanation of the exact causation of this curious phenomenon has been advanced. Personally, I believe that different factors, in different combinations, enter into its causation in different cases. Thus, in a case of Wilson's,² pulsation persisted after the performance of Estländer's operation. Effusion and pneumothorax were certainly not to be considered here, unless we conceive of a possible undiscovered encapsulated effusion in the upper half of the chest, of which there was not the slightest evidence. Adhesion of the lung, especially if atelectatic, to the pericardium might reasonably account for such pulsation.

Edema existed over the greater part of the pulsating region. Paralysis of the intercostal muscles has been prominently mentioned as one of the causes of the pulsation. It has been thought in some cases that the purulent effusion had worked through the muscular tissue, and that the consequent loss of support to the contents of the chest was a factor in its causation. It seems reasonable to suppose that in this case, as in many others reported, the edematous infiltration of the muscle, which caused it in a great degree to lose its contractility, assisted in bringing about the pulsation, the normal elasticity of the muscular walls of the thorax serving to "take up" the pulsating impulse. This theory would apply to cases of empyema also, as an inflammation or edematous infiltration of the diaphragm, which impairs its function and prevents it from acting as an elastic cushion in keeping the contents of the abdomen from encroaching upon the thoracic cavity, might be of importance in the genesis of the pulsation.

¹ Janeway.

² THE MEDICAL NEWS, July 15, 1893.

Féréol's hypothesis, that pneumothorax is an essential element in these cases, certainly could not have applied in this instance, since none of the signs of this affection were present, nor did gas escape from the opening. Increased intrathoracic pressure, an important feature in many cases, did exist, since the fluid escaped in a vigorous jet upon opening the pleural cavity. Toulmin¹ has stated, however, that this increased pressure is not essential.

The latest statistics, as given by Fuchs,² record but eighty-two cases of this condition, the present case bringing the number up to eighty-three. It is thus still sufficiently rare to make the publication of each new case desirable.

THE TREATMENT OF CHRONIC ULCERS BY THE THIERSCH METHOD OF SKIN- GRAFTING.

By JAMES M. PARROTT, M.D.,
OF KINSTON, N. C.

IN all cases of chronic ulcer it is of extreme importance to differentiate between the idiopathic and traumatic origin of the lesion and to institute constitutional treatment in accordance with the findings. As is well known, syphilis plays a very important rôle in the production of ulcers, and if the presence of this disease is even remotely suspected in a given case the patient should at once be placed upon antisiphilitic treatment, and this continued until the system is thoroughly under its influence before attempts at curing the local lesion should be undertaken. Likewise, a patient afflicted with malarial cachexia, in addition to a chronic ulcer, should be placed upon Fowler's solution of arsenic and tincture of the chlorid of iron, and anemic patients should be given a chalybeate preparation during a period of many weeks.

If the ulcer is due to the breaking down of varicose veins, these vessels should be ligated, excised, or obliterated by means of Vienna paste, or a roller or Martin bandage should be worn continually. Tuberculous patients should receive appropriate tonic treatment, and after thorough cleansing the ulcer should repeatedly be dusted with iodoform until it assumes a healthy appearance. The same treatment should be pursued in cases of senile ulcer, and patients suffering from chronic lead poisoning should be given increasing doses of iodid of potash.

The treatment of the ulcer, preparatory to skin-grafting, is of such vital importance that success or failure depends almost entirely upon the faithfulness with which it has been carried out. Infiltrated tissue should be cut away with scissors or knife, and unhealthy surfaces thoroughly curetted. Necrosed bone should be removed, and if eczema has developed near the site of the ulcer the skin should be washed thoroughly with an ethereal soap and borated talcum or powdered oxid of zinc applied. Ordinary soap, grease, and ointments should not be used in this connection.

The instruments necessary in the operation of skin-grafting are few, a sharp razor, two olive-pointed silver

probes, and curved and flat scissors, with, perhaps, a dull curette, answering every purpose. In the way of dressings, a number of cheese-cloth pads, the size of a man's hand, gauze bandages, and a piece of oiled silk is all that will be required. If the surface of an ulcer be covered by healthy granulations, I never hesitate to graft at once, after thoroughly cleansing it with a solution of carbolic acid, or with a 1-to-3000 solution of mercuric bichlorid. These solutions do not endanger the integrity of the grafts, as has been held by certain authorities; the mercurial solution, especially, stimulates the growth of healthy granulations, particularly when applied during the preparatory treatment, and its use is undoubtedly a factor in the good results obtained.

In the application of the dressings one important point should be borne in mind, and that is, the danger which may result from too long-continued use of the oiled-silk protective, maceration of the underlying tissue, and consequent failure of the grafts being a not uncommon sequel. After the grafts have carefully been placed edge to edge over the entire surface of the ulcer, I am in the habit of applying two layers of oiled-silk strips (from a quarter to a half inch in width), the second layer being at right angles to the first, and so arranged that meshes of sufficient size permit of the escape into the gauze pads of any discharge from the ulcerated surface. Maceration or softening of the grafts is thus entirely prevented.

The grafts should be as thin as it is possible to make them, and preferably should be taken from the anterior surface of the thigh, the skin having been thoroughly cleansed and made aseptic. No general rule can be laid down as to the time which should elapse before the wound should be redressed subsequent to the operation, but it is my custom to change the pads and bandages on the second day, and again on the fourth day, at the latter time removing the oiled silk and dusting the surface with subnitrate of bismuth. Two days later, the bismuth is removed and a simple antiseptic dressing applied. The surface from which the grafts have been taken is treated in about the same manner.

The cases here reported in which this method has been employed have been chosen from a score or more, each representing a different form or type of ulcer. I may add that the method in my hands has never resulted in failure, except in one instance, the case being an exceedingly unfavorable one. This patient, however, received great benefit. The Thiersch method is much to be preferred to that of either Reverdin or Wolf. In the Reverdin method the grafts are too frail, and the resulting scar too prominent, while in the Wolf method the grafts are liable to be too thick, and consequently harder to manage and less likely to grow on the new site. According to my experience, the chronic ulcer grafted by the Reverdin method is almost certain to recur.

Cocain will usually answer as an anesthetic in these cases, though general anesthesia sometimes will be necessary in the cases of very nervous individuals and babies.

The cases which I wish to report are as follows:

CASE I.—L. S., aged twenty-one, white. Gave a very positive syphilitic history. When first seen he exhibited

¹ Quoted by Osler.

² *Zeit. für Clin. Med.*, 1897.

a large ulcer on the anterior part of the leg, probably directly produced by an injury received four years previously. He had been unsuccessfully treated by physicians for three years. The ulcer was foul, ragged-edged, and covered with lymph. A poultice of charcoal and flaxseed was ordered and continued for three days, and antisyphilitic treatment was begun at once. On the third day, the ulcer was dressed with moist bichlorid of mercury gauze (1 to 2000), and later, a bichlorid of mercury drip (1 to 5000) was ordered. This was continued for ten days, and, the ulcer then being in a healthy condition, it was grafted by the Thiersch method, the patient being discharged permanently cured, thirty days later.

CASE II.—J. K., aged sixty-two, painter by occupation. When first seen his health was very bad; he was much emaciated, weak, and anemic. Sure and positive symptoms of chronic lead poisoning were exhibited. He had a chronic ulcer of ten-years' standing. The leg was in such bad condition that amputation was at first thought to be necessary. He was given iodid of potash in increasing doses and put to bed, the ulcer being dressed daily for fifteen days with moist 1-to-3000 bichlorid of mercury dressings. This was followed by the bichlorid of mercury drip for four days. The tibia being diseased, it was chiseled and curetted thoroughly, and all of the necrosed bone removed. The mercurial dressings were reapplied and continued for thirty days. Granulations soon formed over the bone, and the ulcer was then grafted by the Thiersch method. The ulcer was three by four and one-half inches in size. In due time the patient was discharged, cured.

CASE III.—M. C., aged sixty-three. When first seen he exhibited a well-marked varicose ulcer on the left leg. The veins were treated very successfully by ligation, and the ulcer prepared by using a daily moist dressing of bichlorid of mercury gauze, preceded by curetting, to remove a heavy coat of lymph and disorganized blood left from frequent hemorrhages. As soon as the granulations formed and became strong (thirteen days after curetting), the ulcer was grafted by the Thiersch method and the patient was cured.

CASE IV.—I was called in consultation to see W. H. T., who exhibited an irritable ulcer, the leg being much swollen and very painful, the patient's temperature being 102.5° F. The ulcer was apparently healthy, but very densely red, the slightest touch causing very acute pain. Save a slight malarial cachexia, the young man seemed to be in good health. The ulcer was of six-years' duration. A moist bichlorid dressing (1 to 3000), preceded by the application of a four-per-cent. solution of cocaine, was applied, and rest in bed, with light diet, ordered. He was given an iron tonic, with Fowler's solution of arsenic. Improvement was very rapid, and eleven days after seeing him I grafted the ulcer by Thiersch's method, with perfect success.

CASE V.—J. L. N., aged seventy-five. When seen this patient had an ulceration about the size of a silver dollar on the left temple, midway between the outer canthus and the ear. A diagnosis of epithelioma, which was afterward confirmed by the microscope, was made.

He readily consented to its removal, which was done the following day. Immediately after the operation the surface was grafted by the Thiersch method and the patient was discharged, cured, almost without a scar. The whole treatment occupied ten days.

CLINICAL LECTURE.

ENDOCARDITIS; ITS DIAGNOSIS AND TREATMENT.¹

By EDWARD F. WELLS, M.D.,
OF CHICAGO;

PROFESSOR OF MEDICINE IN THE CHICAGO POST-GRADUATE MEDICAL SCHOOL.

THAT endocarditis runs its course in a very considerable proportion of cases to well-marked valvular deformity, or, rarely, to a fatal termination, without recognition, is a fact of current information. The necessity for these numerous diagnostic failures I believe to be open to challenge, and the appearance of this patient, with a recently developed endocarditis, affords me an opportunity to call your attention to some of those salient and diagnostic points in the symptomatology of the affection by which it may be recognized, in the vast majority of instances, even in its incipency.

That form of endocarditis which is marked by the appearance of vegetations and which is followed by valvular deformity, and to which my remarks are confined, occurs, usually, as a complication of acute rheumatism, chorea, or tonsillitis; much less frequently in connection with influenza, pneumonia, gonorrhea, scarlatina, erysipelas, puerperal fever, and other infectious diseases; rarely as a primary affection. Acute rheumatism is by far the most frequent cause of endocarditis, and the relationship existing between these, and the resulting valvular deformity as well, is an essential, and not merely an accidental one. Endocarditis occurs in about thirty per cent. of rheumatic attacks—occurring oftener in males than in females; oftener in the young than in the old; oftener in the acute and severe cases, with many joints implicated, than in those pursuing a milder course and affecting only a single joint. It usually appears before the end of the second week, although it may be delayed to a much later date or it may precede or follow the articular manifestations of rheumatism.

The patient before us gives the following history:

CASE I. *Acute Rheumatism; Endocarditis.*—R. W. aged twenty-five, had gonorrhea three years ago, and chancre, without systemic manifestations of syphilis, one year ago. When he first appeared in the clinic he had been ill one week with acute rheumatism, the tarsal joints of both feet being affected. He had slight fever, the temperature being 99.6° F.; normal cardiac action; pulse 82, and a tracing as follows:

FIG. 1.

One week later the temperature was 101° F., and the pulse was about 100, being irregular and dicrotic in character, as shown in the tracing:

¹ Delivered at the Chicago Post-Graduate Medical School.

FIG. 2.

There was also present a marked vibratile tremor of the cardiac region. To-day, after having been sick for one month, his temperature is 99° F., pulse 98, tracing as follows:

FIG. 3.

The cardiac tremor continues and the apex beat has moved outward to the nipple line. There has been no murmur audible, but the mitral first sound has gradually assumed a booming quality which is now quite marked. There have been no subjective cardiac symptoms except a sensation of "quivering," which is noticed only when the patient's attention is directed to the heart.

In the next case the endocardial preceded the articular inflammation:

CASE II. *Endocarditis; Pericarditis; Tonsillitis; Rheumatism; Recovery with Mitral Regurgitation and Compensatory Hypertrophy.*—P.C., aged thirty-seven, an athletic man, was first seen September 30, 1895. During each of the four preceding winters he had had severe attacks of quinsy; aside from this his health has always been good. Two months previously he was taken with chilliness, fever, vomiting, and cough, followed gradually by increasing weakness, cardiac tremor, oppression and cold perspirations on exertion, orthopnea, and dyspnea on awakening from sleep, and cough with free expectoration of bloody serum and mucus. Examination revealed moist bronchial râles generally diffused, increased area of cardiac dulness, with a marked irregular vibratile tremor, indistinct cardiac sounds, with a soft and low-pitched apical systolic murmur, audible only in recumbency, cyanotic and clammy skin, and an anxious expression. The temperature was 98.6° F., and pulse 104 lying, and 112 sitting, with tracing as follows:

FIG. 4.

On October 24th pericarditis, with some effusion and profuse acid perspirations, began, and on November 19th there developed a sharp attack of quinsy. Rapid and decided improvement of general and local conditions followed, with clearer cardiac sounds and more distinct murmur. Early in December the following tracing was made:

FIG. 5.

On January 9, 1896, after exposure, acute rheumatism set in, and affected in turn nearly all the joints of both lower extremities, confining the patient to bed during four weeks.

At the present time, two years after the beginning of his cardiac affection, the patient feels well, and is actively

employed. There is palpitation and oppression only upon excessive exertion. The murmur is present, and the action of the enlarged heart is powerful. The tracings are now as follows:

FIG. 6.

This when at rest. Moderate exercise, such as walking half a mile, changes the character of the pulse as shown in the next tracing:

FIG. 7.

It is quite clear that there is yet a lack of that nicety of balance and reserve force which further cardiac hypertrophy may bring about.

In the next case the endocarditis followed the subsidence of the acute rheumatic symptoms:

CASE III. *Rheumatism; Hemoptysis; Herpes Zoster; Tonsillitis; Endocarditis, followed by Mitral Insufficiency.*—Mrs. S. W., aged thirty-five, was inoculated with syphilis at twenty-nine, which resulted in cutaneous eruption, loss of nails, etc., but after two years there were no further manifestations noticed. On December 23, 1892, she was taken with a chill, followed by high fever and pain in the right thumb. On the fifth day the left knee became affected and here, with some temporary shifting, the seat of local inflammation remained throughout the illness. During the first week there was much delirium, with hallucinations. On the fourteenth day there was hemoptysis to the extent of half an ounce, without cough or other premonitions. On the seventeenth and eighteenth days there was agonizing pain in the epigastrium, with vomiting and hiccough. There was permanent subsidence of the fever on the twenty-fifth day, with pain only when the knee was moved. She first walked on the fifty-sixth day. On March 17, 1893, herpes zoster developed on the left side of the chest. On March 27th, tonsillitis developed, with high fever for forty-eight hours. Following the tonsillitis there was considerable prostration, with profuse non-acid perspirations during sleep. On April 10th there was a cardiac tremor and the pulse was rapid and dicrotic. On May 23d, a blowing systolic murmur was noted in the mitral area. One year later there was anemia with palpitation and oppression on exertion, and with dyspnea when lying supine, especially when tired.

During the entire course of the illness careful examinations were made of the heart and pulse, once or twice daily during the acute stages, and once or twice a week subsequently, and at no time previous to April 10th were there any symptoms indicative of endocardial involvement, and this applies also to examinations made previous to the rheumatic attack. Numerous sphygmographic tracings were made, selections from which, with dates appended, are shown:

FIG. 8.

December 27th—Fifth day.

FIG. 9.

January 4th—Thirteenth day.

FIG. 10.

January 10th—Nineteenth day.

FIG. 11.

February 5th—Forty-fifth day.

FIG. 12.

April 10th—Endocarditis.

FIG. 13.

May 26, 1894.

The diagnosis of endocarditis is seldom made with ease. By carefully reviewing all the features of the case its presence may usually be recognized, either positively or with reasonable assurance, although in a certain proportion of cases it must run its course unsuspected. Subjectively the cardiac or other sensations in endocardial inflammation are not of a nature to direct the patient's attention toward his heart; yet, discrete and careful questioning will often elicit information as to symptoms, which, taken in connection with others, are suggestive and of diagnostic importance. Thus, although pain is rare in uncomplicated cases, there is frequently present, in the region of the heart, an undefinable sensation of heaviness or discomfort. Thoracic oppression, perhaps with palpitation, on suddenly changing the posture is often noticed. Weakness is almost always a marked feature.

Objectively you will find the symptoms much more distinctive. Elevation of the corporeal temperature, which is usually moderate, rarely high, sometimes very slight, but almost always positive, is an important symptom and may be the only one present. In the course of an attack of acute rheumatism or other disease which is liable to be complicated by endocardial inflammation, an increase of temperature, or its persistence at a time when it should subside, without other obvious reason is a suspicious circumstance. The type of the fever is usually an irregularly continuous one, although in some cases it may be remittent, intermittent, or erratic. Careful study of the pulse, with the finger, and especially with the sphygmograph, will furnish information of the greatest diagnostic value. For the patient, the individual characteristics of his pulse are usually radically and permanently changed. The primary change is due to cardiac irritability and, later, to myocardial weakness, while the secondary ones are chargeable to the consequences of valvular insufficiencies. In frank cases the early alterations of the pulse are very marked and will scarcely escape your notice. The pulse is accelerated, the arterial expansion is great but the ten-

sion is low, diastolic is often present, and the rhythm may be irregular, either constantly or at times. The pulse alterations bear no relation to the stage or state of the rheumatism or other primary affection, or to the general condition of the patient. Changes in the heart sounds usually appear after the endocarditis has existed for a considerable time, although they occasionally develop with remarkable rapidity, or they may be long delayed, evanescent, or may remain absent. The murmurs which you will observe oftenest and earliest are a systolic apex murmur, which arises suddenly, and diastolic murmurs, which are variously located and gradually developed. These murmurs are of very uncertain value when they are employed as measures of the extent and severity of the valvular inflammation. However, in my own experience, loud and obstrusive murmurs which have arisen early, during the febrile period, have been of uniformly bad augury. A recent endocarditis may have its signs obscured by a previously existing valvular deformity or by those due to a complicating endocarditis. The occurrence of embolism, erythema nodosum, or chorea, should always lead to inquiry as to the presence of endocarditis.

The treatment of endocarditis demands your most serious consideration, but its prevention will first engage our attention. Usually endocarditis is an early complication of rheumatism, chorea, and allied diseases and, therefore, if prophylactic measures are to be of any service whatever they must be promptly instituted. Abundant experience has shown that salicin, salicylic acid, and salicylate of soda are useful antirheumatic remedies, and one of these should be given in full doses. Forty years ago the theory, which was apparently demonstrated, was that the endocarditis was due to the effects of free lactic acid in the circulation, and, inasmuch as rheumatic patients continue to have acid perspirations, you will not be amiss in prescribing alkalis. Recent investigations point more or less strongly toward the bacterial origin of the valvular inflammation and you may desire to introduce a bactericide into the circulation. Sulphuretted hydrogen is an agent of this class which may safely be employed in large and probably efficient doses. "Washing the blood," by draining away the serum by hydrogogue cathartics and restoring the volume of the blood by large hypodermic injections of normal saline solution or, more certainly by venesection, followed by intravenous injections of saline solution, is a measure worthy of being given an extended trial. To soothingly modify the irregular, excited, and embarrassed action of the heart, and to transfer the bulk of the blood to the venous side of the circulatory system, veratrum viride should be given. In addition to the special measures which have been mentioned, the patient should have careful nursing, with, as far as is practicable, mental and physical rest, and confinement to the bed or couch. The skin should be kept gently acting, with hot air or sponge baths, or dry rubbing, as may be indicated, and the surface should be covered by suitable woolen underclothing and protected from draughts. The bowels should be kept open, with occasional free catharsis, and the kidneys stimulated to free action. The diet should be light and nutritious, with an abundance of fluids.

In private practice, for an adult with acute rheumatism, I usually write the following prescriptions:

℞ Sodii salicylas 3 iv
Fl. ext. verat. virid. gtt. xcvi
Ol. menth. pip. gtt. vi
Elix. simp. rub., q.s. ad 3 iii.

M. Sig. A teaspoonful every two to four hours, as directed.

The nurse is directed to give the medicine every two hours at first, but to lengthen the interval if the ears should become affected or nausea ensue.

℞ Calcii sulphid (Merck's) 3 ii
Ulmus pulv. 3 i.

M. (dry), ft. supposit. (using hollow suppositories) No. xx. Sig. One, three, or four times a day.

Should endocarditis be already present in its early stages, or develop in the face of your well-directed preventive efforts, the treatment above outlined still is indicated. After a few days the veratrum viride will certainly, and the salicylate will probably, require to be diminished in dose or altogether suspended. They should, however, be resumed with recurring indications or any tendency to relapse. With the subsidence of the fever and other symptoms of inflammation, the sulphid of lime should be discarded and agents employed which may promote absorption of inflammatory exudates. For this purpose iodid of potassium has largely been given, but I prefer to use corrosive sublimate. At this period in the progress of the case there generally is present anemia and, with advancing valvular insufficiency, dilated chambers and a weakened myocardium. To meet these indications, the patient should have rest with, possibly, passive exercise, a nutritious diet which is not bulky and contains as little fluid as possible, and a prescription as follows:

℞ Strychniæ gr. i
Hydrarg. chlorid. corrosiv. gr. iss
Ferri redact. gr. xxx
Digitalis ext. gr. x
Gentian ext. q.s.

M. ft. pil. No. xxx. Sig. One pill three times a day for five days in each week.

With the disappearance of all inflammatory action and cessation of the deposition of fibrinous exudates upon the surface of the valves and in the fibrous tissue of the rings, and the gradual development of the full measure of valvular insufficiency, with compensatory hypertrophy, or, unfortunately, uncompensated dilatation, other and vitally important problems are offered for solution, but these fall beyond the scope of this lecture.

MEDICAL PROGRESS.

Lavage of the Blood Through the Medium of the Stomach.—MAUSEL suggests (*Rev. d. Thérapéut.*, May 15, 1897) that in the discussion about the "lavage of the blood," which can be accomplished by subcutaneous and intravenous injections of artificial serum, the use of the digestive tract as an agent for absorption has been overlooked. Absorption by this route is less rapid, but equally as sure, as by the other, and the subsequent diuretic ac-

tion is just as efficacious. This is the revival of the administration of "cooling draughts."

Preliminary blood-letting is important, as it removes a part of the poisonous material and also favors the absorption of the saline solution into the circulation.

Beneficial Effect of Ingestion of Lung in Pulmonary Tuberculosis.—GRANDE (*Rev. d. Thérapéut.*, May 15, 1897) wishing to give to a patient, suffering from phthisis in the second degree, one pound of healthy lung tissue daily, found that its equivalent was from 4 to 5 grams (1 dram) of the dessicated pulmonary tissue, which he administered in tablets. This treatment was continued for five months. During this time the cough nearly vanished, bacilli became rare in the sputum, and the patient gained twelve pounds in weight.

A series of control experiments was conducted with guinea-pigs, three of which were inoculated on November 7, 1896, with tuberculous sputum. One of them, receiving no subsequent treatment, died in fifty-three days with disseminated tuberculosis of the lungs, liver, and spleen. The other two were treated with the powdered lung, boiled in distilled water and then filtered. Three months after the inoculation they were living, presenting no sign of tuberculous trouble, and apparently well.

Granular Ophthalmia Treated with a Mixture of Guaiacol and Glycerin.—For a year past BENTÉJAC (*Rev. d. Thérapéut.*, May 15, 1897) has treated all the cases of granular ophthalmia at his eye clinic with a mixture of guaiacol and glycerin, 1 to 100 or 1 to 200. All of the patients who persisted in the treatment received greater or less benefit.

The advantages of this remedy are its powerful congestive action and its freedom from danger and pain. Under its use the mucopurulent secretions diminish and disappear, and with these vanish the superficial ulcers of the cornea. The pannus grows thin and disappears altogether after one or two months. One or two applications are made each day, or one application may be made in the morning and a soothing application in the evening.

As a result of this treatment the circulatory activity is greatly increased, the granulations are vascularized and the infective agent and its toxins are discharged. Caustics act in the same way, but their destructive chemic action makes one dread their contact with corneal ulcers—a fear which is not present when a weak solution of guaiacol is employed.

A Quick Method of Epilation in Tinea.—According to JOLKOFF (*Rev. d. Thérapéut.*, May 15, 1897), epilation in tinea can be greatly facilitated by the use of strong adhesive plaster, applied warm in strips over the affected areas. When thoroughly cool these strips are peeled off in the direction opposite to that in which the hairs grow, *e. g.*, from the forehead backward for the frontal region, and from the neck upward for the occipital region. If this precaution is observed the plaster will extract the affected hairs while leaving the sound ones.

Operative Treatment of Pott's Disease with Deformity.—LANGE has modified Calot's *redressement brusque* in Pott's

disease (*Münch. Med. Wochenschr.*, April 20, 1897). The originator of this plan of treatment put the chloroformed patient on his face, and while two assistants made strong traction on the head and feet, and two others supported the chest and pelvis, Calot pressed with all his strength on the greatest prominence of the deformity until it gave way, and with a loud crack the spine straightened out. A plaster-of-Paris bandage was put on from head to pelvis and worn three or four months, and then renewed and followed by a corset. Calot has not had any paralysis as a result of this treatment. If the spinous and transverse processes are fairly well preserved the result of this straightening of the spine is to give more room for the spinal cord.

Lange believes a considerable part of the improvement which followed Calot's treatment is due to the situation of his hospital beside the ocean. His method of procedure is to put on the day previous the portions of the bandage which surround the head and pelvis. This shortens the period of narcosis considerably. Then by suspending the patient by a couple of bands in a horizontal position two of the assistants may be dispensed with.

THERAPEUTIC NOTES.

The Practical Importance of the Gonococcus.—Neisser has shown the importance of a microscopic, instead of a macroscopic, examination in order to make a diagnosis of gonorrhea in the female. In the medical examination of prostitutes in German cities, this plan has been followed only in Breslau, and more recently in Stuttgart. In the latter city, according to HAMMER (*Centralbl. für Chirurgie*, May 15, 1897), the urethral secretion is examined every week, and that from the cervix every four weeks. Those women in whom gonococci are found are placed in the hospital for treatment. The uncertainty of a macroscopic examination was at once shown, and since the introduction of the microscopic method the number of prostitutes treated in the hospital for gonorrhea has greatly increased.

The author recommends treatment of the urethritis with ichthyol. For uterine gonorrhea he employs a swab saturated with a five- or ten-per-cent. solution of chlorid of zinc. Infection of Bartholin's glands is treated by cauterization with nitrate of silver fused upon a probe.

For the Bronchial Catarrh of Heart Disease.—

℞	Ammoniac	} aa	3 ii
	Tinct. tolut.		
	Tinct. digitalis		3 i-ii
	Morphinæ sulph.		gr. ss
	Pulv. acaciæ		3 ii
	Aquæ, q.s. ad		℥ vi.

M. Sig. One tablespoonful every three or four hours.

The Following Formula for the Administration of Diuretin is Recommended:

℞	Diuretin		4-6 parts
	Aq. menth. pip.		100 parts
	Aq. destillat.		90 parts
	Syr. simp.		10 parts.

M. Sig. Two tablespoonfuls every two or three hours.

For Gastralgia.—

℞	Codeinæ sulphat.		gr. iii
	Ext. cannab. indic.		gr. ii
	Ext. nucis vom.		gr. iii.
	Ft. Pil. No. XII.		

M. Sig. One pill three times daily after meals.—*Ashton.*

An Excellent Sedative Antipyretic Mixture for a Child.—

℞	Antipyrin		gr. xxiv
	Sodii bromidi		gr. xlv
	Syr. lactucarii		℥ ii.

M. Sig. 3 ss. when necessary for restlessness.

A Useful Sedative in Simple Endocarditis is the Following Combination:

℞	Tinct. Aconiti		m. xxiv
	Potass. bromidi		3 ii
	Aq. camphoræ, q.s. ad		℥ iii.

M. Sig. Two teaspoonfuls every two hours.—*Henry.*

A Good Diuretic Mixture in Heart Disease Where Digitalis is not Contraindicated is the Following:

℞	Pulv. digitalis	} aa	gr. xx
	Pulv. scillæ		
	Pulv. scammonii		gr. xl.
	Div. in chart No. XX.		

M. Sig. One powder three times daily.

Lotion for Facial Erysipelas.—

℞	Carbolic acid	} aa	2 parts
	Tincture of iodine		
	Alcohol	}	4 parts
	Turpentine		
	Glycerin		6 parts.

M. Sig. Apply every two hours and cover with sterilized gauze.

Camphor as an Antigalactagogue.—HERRGOTT (*La Semaine Méd.*, June 2, 1897) has prescribed camphor in order to dry up the milk of mothers who do not desire to nurse their children. It is given in doses of six grains three times a day for three consecutive days. In thirty cases in which it was employed the results were almost invariably swift and satisfactory.

Antipyrin and Arsenic in Chorea.—According to MARFAN (*La Presse Méd.*, May 29, 1897), the best results are obtained in the treatment of chorea from the use of antipyrin and arsenic administered in the following manner: Antipyrin should be given in a liquid, the daily dose being divided into three equal parts, one to be taken with each meal. Beginning with a daily dose of forty-five grains, fifteen grains in addition are given each day until ninety grains are reached. This amount is given daily until the choreaic movements have notably diminished. Fifteen grains less of the medicine is then given each day until forty-five grains are reached, at which point the medication is continued for some days longer.

There are a few obstinate cases of chorea which are not affected by antipyrin, but which yield to continually increasing doses of arsenious acid, best given as Fowler's solution, well diluted. The dose may be increased until symptoms of intolerance appear or until half a grain of the acid is given daily. Children usually bear large doses of arsenic well. If it is necessary to add to this treatment a hypnotic, chloral will be found of service.

SATURDAY, JULY 31, 1897.

MOVABLE KIDNEY.

At a recent meeting of the American Association of Genito-Urinary Surgeons, held in Washington, an interesting and instructive discussion occurred upon the subject of movable kidney.

Three papers bearing upon this subject were presented. The first of these was read by Dr. Francis S. Watson of Boston, who gave the results of some interesting observations made during a series of *post-mortem* examinations upon subjects having well-marked evidences of this condition. Thirty-eight subjects chosen at random in the dissecting-room were examined. In eight of these movable kidneys were found; four in the male, and an equal number in female subjects. In five of these the peri-renal fat was markedly diminished. In four of the eight there were well-marked evidences of ptosis of other organs. Dr. Watson called especial attention to the fact, that kinking of the ureter, which is supposed to give rise to colic, nausea, and urinary disturbances, was more easily caused by a rotation of the displaced organ, than by simple descent.

The second paper, entitled "Clinical Observations on Loose and Displaced Kidney," by Dr. John

P. Bryson of St. Louis, brought out several interesting facts. From a number of careful observations made upon living subjects during operations, he also was led to believe that rotation of the organ was responsible for most of the painful symptoms observed during the acute attacks. He was convinced that the attacks of pain were, in the majority of instances, due to congestion of the organ, from twisting of the blood-vessels, rather than to an accumulation of urine in the pelvis from kinking of the ureter. In his experience, gastric symptoms were only associated with displacements or lesions of the right kidney, and could be explained by the intimate connection between the right kidney and the duodenum. An observation which had invariably forced itself upon him was that frequent and painful micturition, when associated with this condition, was always due to a kinking or lesion of the ureter, in its lower segment.

The third paper, by Dr. Brewer of New York, entitled "Some Observations upon the Surgical Anatomy of the Kidney" is published in the present number of the NEWS. In this the writer records the result of two hundred clinical and one hundred and fifty-one *post-mortem* examinations. In his clinical series of observations, displaced kidneys were found in 5.5 per cent. of all the cases; in 14 per cent. of the males and in 17.3 per cent. of the females—in every instance upon the right side.

These observations are in accord with the generally accepted view that renal dislocation is found most frequently in women, and upon the right side. In his *post-mortem* examinations, however, displaced kidney was found twice as frequently in males as in females—a fact not hitherto observed.

It is to be hoped that these papers and the discussion which followed, will serve to draw the attention of the medical profession to this frequent cause of suffering in both sexes, and to correct in a measure the general impression which has been held by many, and not infrequently expressed by the general surgeons, that movable kidney was a gynecologic fad.

THE EMPLOYMENT OF PRISONERS.

ABOUT two years ago THE MEDICAL NEWS, in commenting upon this subject, said: "We do not know of any example of popular legislation that equals in folly and wickedness an amendment to the New York

State Constitution recently offered to the people for ratification which prohibits the employment of prisoners at productive labor."

It was pointed out that the folly of this act consisted in depriving the State of the benefit of labor which was making its penal institutions nearly self-supporting, and its wickedness in immuring prisoners in solitary cells who, without labor, must necessarily undergo physical, mental, and moral deterioration.

The truthfulness of this exposition was to be vindicated more promptly than the writer knew. It is not an unusual thing for inmates of penitentiaries to become insane, for it is a well-founded belief that many perpetrators of crime are at the time of their unlawful acts suffering from more or less mental derangement. But the remarkable increase in the number of those who have become insane in the State penitentiaries since the law prohibiting convict labor went into effect, points strikingly to a lack of employment as the predominating cause.

A commission recently appointed to inquire into the sanity of suspicious prisoners held in the Kings County Penitentiary pronounced no less than seven out of twenty, hopeless maniacs. Since January 1, 1897, the average number of prisoners in this institution has been 775; during this time 18 have become insane. Comparing this with the same period of the previous year, we find that the average number of prisoners at that time was 1200, 19 of whom became insane. It will therefore be seen that with nearly fifty per cent. less convicts in the prison during the last seven months, there has been only one less case of insanity. Moreover, in not a single case of the seven men above referred to who have become insane during the latter period, can there be found a trace of hereditary or occasional insanity previous to their incarceration, and all have become insane since the new law went into effect. It is a striking fact that only one woman has become insane in this institution during a period of four years. But the women are never idle, being engaged in scrubbing, cleaning, washing, and mending or making clothes. On the other hand, the majority of the male convicts are confined to their cells twenty-two out of the twenty-four hours of every day.

The state of affairs existing in Kings County Penitentiary is no exception to what is being experienced in the other penal institutions of the State; nor

can any responsibility for the large number of prisoners who have become insane be ascribed to improper management of this institution. The officer who inspects State prisons where Federal prisoners are confined, stated in his last report that the Kings County Penitentiary was the best appointed and best conducted of all prisons in this country where Federal prisoners are incarcerated.

The sufferings attendant upon the method of confinement made necessary by the present law can only be appreciated by those who are compelled to guard these wretches as they sit in their solitary cells conscious of the horrible fact that reason is gradually slipping away. The horrors of the situation are brought home to us in the account as given in the *New York Sun* of one of the prisoners in the institution mentioned, who before his incarceration had given evidences of rather unusual cleverness, although, unfortunately, his inventive genius was directed to unlawful ends. He had invented a sort of "jimmy" very useful in opening safes. About a year from the date of his confinement the warden noticed that this prisoner was becoming morose and melancholy. One day the keeper told him to cheer up. "Cheer up! cheer up!" he said. "Ah! that is easy for you to say with plenty of work to do. Give me something to occupy my mind save my own miserable thoughts and I will take a brace. If you don't give me something to do, some day I will cheer you with the howls of a maniac. I am going mad—I know it—but all I can do is to watch my reason slip away. That's a thought to cheer a man, isn't it?" Within a month from that time the wretched prisoner's premonitions were realized.

A similar fate awaited another prisoner, who has always stoutly maintained his innocence, and whose friends are so convinced that he is innocent of the crime for which he was sentenced that strenuous efforts have been made to secure his pardon. With nothing to occupy the man's mind save the thought of his pardon, and with hope deferred from day to day, his reason broke down under the strain and suddenly, instead of stoutly maintaining that his pardon would soon arrive, he greeted his keepers one morning with a wild glare, made a dash for the barred door, and fastened his teeth in the grating. Then he started back yelling, "I eat pardons, I do, and I eat the devils that grow them. I have

gone mad, I have. To hell with pardons. Lunatics cut their throats with pardons."

Such scenes as these are familiar occurrences in asylums, but when the responsibility for the de-thronement of reason clearly rests upon the administration of unwise laws it is time for the community in which they occur to pause and consider.

It must not be forgotten that the object of penal institutions is not to rob men of their reason, but to protect the community from those who are too vicious to be allowed their freedom, and to throw about them all such disciplinary provisions as will engender in them industrious habits with the hope that they may be restored to healthful citizenship.

ECHOES AND NEWS.

Plague-Stricken Bombay.—It is reported that there has been an alarming increase of death from cholera in the Bombay Presidency and some recrudescence of the bubonic plague.

Death from Antipyrin.—A death after taking two 10-grain doses of antipyrin is reported from England. The drug was taken by a chemist's assistant for the relief of neuralgic toothache.

Death of Dr. Oliver S. Flint.—Dr. Oliver S. Flint recently died of neuralgia of the heart at his home in Hartford, Conn., in his sixty-fifth year. He had been in practice more than thirty years.

Scarlet Fever in a Sweat-shop.—It is reported from Albany that a factory inspector has recently discovered two cases of scarlet fever in a sweat-shop in Brooklyn where clothing was being manufactured.

An Appropriation for the Kings County Hospital.—The Aldermen of Brooklyn have appropriated \$17,000 for the construction of a new administration building for the Kings County Hospital at Flatbush.

Old Age in Massachusetts.—According to the census of 1895 there are thirty-five centenarians in the State of Massachusetts. Of this number thirty are women. The oldest one of all, however, is a man, aged 111 years.

Oculist to Examine the Kaiser's Eye.—Duke Charles Theodore, the Bavarian royal oculist, has been summoned to Kiel to examine Emperor William's eye, which was recently injured by a swinging rope on the Imperial yacht.

Newport Hospital Appointments.—The following have been elected consulting physicians to the Newport R. I. Hospital: Drs. W. T. Bull, E. S. F. Arnold, Clement Cleveland, H. E. Knapp, H. R. Storer, and H. G. Mackaye.

Leprosy in Jersey City.—The Board of Health of Jersey City has recently ordered the removal to the pest-house

of a man suffering from leprosy. The patient is a man, thirty-six years of age, who has the disease in its tuberculous form.

Foreigners May Become Doctors.—The Supreme Council of Education in Paris has adopted a provision by which foreigners are enabled to obtain a doctor's diploma, permitting them to practice in France, by undergoing an examination at French universities.

Death of Dr. W. Thomas Atkins.—The death of Dr. W. Thomas Atkins of Toronto has recently been announced. Dr. Atkins was for many years surgeon to the Toronto General Hospital, and was President of the Toronto Medical School for nearly twenty years.

No Medical Registration in India.—There is no medical registration in India, nor is there any Medical Act in that country to govern or regulate the conduct of practitioners of medicine, to protect them in the exercise of their calling, or to defend the public from quackery in its many guises.

Bubonic Plague at San Francisco.—A ship recently arrived from Calcutta is held in quarantine at San Francisco on account of the presence on board of what is supposed to be bubonic plague. One of the crew died during the voyage from Calcutta, and two of the men are ill with the same disease.

Indian Barracks Disease.—The news comes from Simla that the Vice-Regal Legislative Council has adopted a bill restoring the Cantonment Act of 1889. The object of this action is to restore to the Governor-General in Council power to regulate prostitution and check the spread of venereal disease in the Indian army.

Knocked Speechless.—A Hudson county, N. Y., girl was knocked speechless not long ago by being run into by a bicycle. She was otherwise badly injured, and it was thought that she would not recover, but she has gradually improved and now is practically in normal health, except that she has not recovered her speech.

Bullet in the Pericardium Located by the X-Ray.—A lateral skiagraph was recently made of the upper portion of the body of a Chicago man who had been shot in the breast. The photograph showed the bullet firmly lodged in the pericardium, it having followed a downward course for a distance of two inches after entering the thorax.

Camp Cholera at Sea Girt, N. J.—It is reported that this disease has assumed the proportions of an epidemic at the New Jersey State camp, there being at one time more than 200 men under treatment. The regimental surgeons believe the epidemic to be due to a combination of miserable weather, artesian water, and too much "high jinks."

It may Prevent Contagion.—At a recent meeting of the Board of Aldermen, a resolution was passed requesting the Commissioner of Street Cleaning to provide paper bags for accumulations of paper, especially in tenement houses, these bags not to be returned. This arrangement, it is hoped, may assist in preventing the spread of contagious diseases.

Koch on the Bubonic Plague.—Professor Koch has made a report giving the result of his investigations into the bubonic plague. Experiments were made upon 1400 cases. He says that the bacillus possesses but little vitality outside of the bodies of men and animals, and adds that Professor Haffkine's serum possesses undoubted protective qualities.

Death of Surgeon-General Herbert Taylor Reade, V.C., C.B.—The death at Bath, Eng., of Surgeon-General Herbert Taylor Reade, V.C., C.B., Honorary Surgeon to the Queen, has been announced. He was born in 1828, entered the army as an assistant-surgeon in 1850, and retired with the rank of surgeon-general in 1887, at which time the Queen created him a C.B.

A Therapeutic Bacillus.—In an official report made to the Colonial Government by Mr. Hankin of India is described a new bacillus which has recently been discovered by a young Parsee physician, Dr. Ghadiali. This bacillus is said to have the peculiar power of destroying the enteric and other allied micro-organisms. The microbe has been named the "micrococcus Ghadiali."

Deceptions to Avoid Discovery of Plague.—According to the *British Medical Journal* the natives in India resort to all sorts of devices to avoid detection of cases of plague in their dwellings. In one instance a party of searchers discovered a number of natives playing cards and among them was a dead man who had been hurriedly propped up and a few cards thrust into his hand.

No Sunstrokes in Texas and Arizona.—In these days of sunstroke in the North and East, the distant parts of the country are congratulating themselves. The *Galveston (Texas) News* proclaims that there has not been a death or prostration from heat in Texas this summer, and the *Phoenix (Arizona) Republican* says that in that Territory prostrations from heat are unknown.—*N. Y. Times*.

An English Quack Punished.—The maker of a "patent truss" in England was recently sentenced to eighteen-months' imprisonment at hard labor for defrauding the public. By means of misleading advertisements and testimonials appropriated from the trade circulars of various truss-makers, many persons were induced to purchase a worthless article at double the price charged for a good truss.

Mouth Breathing in Consumption.—According to an English observer, nearly fifty-five per cent. of the population are mouth-breathers. Phthisical patients, who readily tire and get out of breath, are especially liable to form this habit and to be injured by it. They should therefore either live in places protected against dust and wind, or should wear respirators whenever the weather is unsuitable.

The Annual Meeting of the Chautauqua County Medical Society.—The annual meeting of this Society was held at the Hotel Athenæum, Chautauqua, N. Y., on July 13, 1897. The following officers were elected for the ensu-

ing year: President, Dr. Morris N. Bemus; vice-president, Dr. V. M. Griswold; secretary and treasurer, Dr. Charles A. Ellis, Delegates to State Society meeting: Drs. E. S. Rich and C. A. Ellis.

In Jail for Signing Fraudulent Medical Certificates.—The news comes from Harrisburg, Pa., that Dr. W. L. Duff, a practitioner of long standing, has been sentenced to three months in jail for signing fraudulent medical certificates attached to applications to the Mutual Life Association of Binghamton, N. Y. The applications were forgeries and the physician made no examination of the persons named in the certificates.

The New General Hospital of Hamburg.—Dr. A. Jacobi, chairman of the American National Committee of the Twelfth International Medical Congress, is in receipt of a letter from Dr. H. Kümmell, surgical director of the New General Hospital (Neues Allgemeines Krankenhaus) of Hamburg, inviting American physicians who attend the Congress at Moscow to stop at Hamburg and inspect the hospital and the new hygienic establishments.

The Jubilee and Women Doctors.—In connection with the jubilee, the compiling of the advances and progress of medicine during the past sixty years, recalls the fact that in 1859 the first female physician, Dr. Elizabeth Blackwell, was registered in England. It was not until 1865, however, that an English medical diploma was granted to a woman—Mrs. Garrett Anderson. In 1892 women were admitted to membership by the British Medical Association.

Medal of Honor to Dr. Blackwood.—The news comes from Washington that Dr. William R. D. Blackwood of Philadelphia has received a medal of honor for most distinguished gallantry at Petersburg on April 2, 1865. Dr. Blackwood was surgeon of the Forty-eighth Pennsylvania Volunteers, and the medal was conferred for "removing severely wounded officers and soldiers from the field while under a heavy fire of the enemy, exposing himself beyond the call of duty."

Electric Clarification of Wine.—Otho Reinke, in the *Wochenschrift für Brauerei*, describes a new process for the clarification of fermented liquors. It was found that clarification takes place rapidly if a vessel containing wine or beer in the process of fermentation be illuminated by sunlight, and Herr Reinke was led by this fact to try the effect of electric light with the result that he obtained rapid and complete clarification by hanging arc-lamps near the fermenting liquors.

London's Thirst.—Despite its house water supply, its 712 drinking fountains used daily by 2,500,000 persons (to say nothing of 476 small troughs for dogs and sheep, and 286 large troughs which are patronized by 500,000 horses), London consumes daily 485,000 gallons of beer, or 177,000,000 gallons yearly; 5500 gallons of wine, 16,000 gallons of spirits, 187,000 of aerated water, and as much tea as can be drawn from 8000 pounds, besides coffee, cocoa, and other beverages.

Dr. Janeway in Bellevue's Faculty.—It is officially announced that Dr. E. G. Janeway has been elected Professor of Medicine and President of the Faculty of Bellevue Hospital Medical College. The other professors in the department of General Medicine are as follows: A. A. Smith, M.D., LL.D., Professor of Principles and Practice of Medicine and Clinical Medicine; H. M. Biggs, M.D., Professor of Therapeutics and Clinical Medicine and Adjunct-Professor of Principles and Practice of Medicine.

The Indian Territory Medical Association.—At the regular semi-annual meeting of the Indian Territory Medical Association, held at South McAlester, I. T., June 29 and 30, 1897, the following officers were elected for the ensuing year: President, Dr. E. N. Allen, South McAlester, I. T.; first vice-president, Dr. G. W. West, Eufala, I. T.; second vice-president, Dr. J. B. Rolet, Oklahoma City, O. T.; secretary, Dr. LeRoy Long, Caddo, I. T. The next meeting of the Association will be held at Muskogee, I. T., December 7 and 8, 1897.

Surgery to Make a Cruel Cure.—Three years ago a man in St. Louis shot and killed his sweetheart and then attempted unsuccessfully to take his own life. His skull, however, was fractured by the bullet. Upon his recovery, he was tried and sentenced to be hanged, but while awaiting the day of execution the man became insane, and has been in an asylum ever since. As his insanity is supposed to be due to the presence of new bone at the site of injury, it is proposed to remove this, after which, if he recovers his reason, he will be returned to the prison authorities and duly hanged.

He Wants the Rouss Million.—An Englishman, who has lived in India for forty-two years, where he has mastered the mysteries of Oriental occultism, is desirous of coming to New York to restore the eye-sight of Charles Broadway Rouss. Mr. Rouss, however, does not believe in the miraculous powers of the man to the extent of paying the traveling expenses of the healer and his retinue, which would amount to about \$10,000, so he has telegraphed him not to come. The offer of \$1,000,000 to anyone who will restore Mr. Rouss' sight still holds good, however. His loss of sight is due to atrophy of the optic nerves.

Floating Hospital Struck by Lightning.—The Floating Hospital of St. John's Guild, New York City, was struck by lightning while coming up the bay one day last week. A child was killed in its mother's arms and the premature birth of a baby was caused by the same shock. Dr. Charles Leale who examined the body of the dead child found a red dark mark three inches wide and fifteen inches long on the skin over the spine, with a blistered spot at the end of the streak. The child's dress was burned as if by fire. The new-born baby was also found to have a red streak three inches wide along the back of its head and down the spine:

Disease in Athens.—Dr. Zavitziano, the United States Sanitary Commissioner, now in Greece, reports to Sur-

geon-General Wyman that over 25,000 refugees have crowded into Athens from Thessaly and Epirus, and it is feared that the Sultan's delay in accepting the ultimatum of the powers may result in a sweeping epidemic. Nearly 20,000 of the refugees are dependent on charity for daily food. The water is of poor quality and not abundant and with the slightest wind the town is enveloped in clouds of dust, spreading infection and favoring consumption, which latter already causes thirty per cent. of the deaths in Athens.

No Appropriation for Medical Investigation.—A supply bill recently passed by the New York Legislature contained an item appropriating \$10,000 for the Medical Department of Buffalo University to investigate the causes, nature, and treatment of cancer. Governor Black, however, vetoed the appropriation, saying, "I cannot approve a proposed policy which requires the State to engage in an investigation of the causes of various diseases with which the human family is afflicted. I think that the interests of the people themselves and the skill, intelligence, and enterprise of physicians may be depended upon to make an investigation."

Statistics of Carbolic-Acid Poisoning.—It is suggested that some restriction be placed upon the sale of carbolic acid on account of the fact that of late years it has so frequently been used for suicidal purposes. Dr. Dixon Mann, in an article in the May number of the *Medical Chronicle*, shows that one-third of the males and very nearly one-half of the females who poisoned themselves during the year 1895, did so with carbolic acid. In other words, out of a total of 580 deaths from poison, no less than 224 were due to the use of carbolic acid. The inference is that the ease with which the drug can be procured acts as a direct incentive to suicide.

Is Murder on the Increase?—The statistics of the superintendent of New York State prisons show that the number of executions in this State has greatly increased since the electrocution law took effect in 1890. Forty executions have occurred since that date, while there were but 230 hangings in the history of the State before that time. This is an increase of 200 per cent. and more. The increase is supposed to be due to one or both of the following causes: Juries, believing in the humanity of the present system of execution, are more willing to convict, and the place of execution being removed from the county where the criminal is known, there is less likelihood of applications for executive clemency.

Plague Ship Wrecked.—Word comes from Liverpool of the arrival there of the widow of the captain of the fever-smitten British ship "Traveler," which was wrecked February 4th off Rodrigues Island in the Indian Ocean, 330 miles from Mauritius. The ship was bound from Java to Delaware Breakwater, and soon after leaving the former port Java river fever attacked everybody on board, and many died. Only two of the crew with the mate were able to work when the ship neared Rodrigues Island. A pilot refused to board the vessel when he learned of the

pestilence, and upon his return to the island reported that all on board were stricken with yellow fever. They were not allowed to land, and no assistance was given them. That night the ship was wrecked on a reef. The survivors were then taken off and transferred to a desert sand island, where they were quarantined for twenty-two days.

Medical Inspection of Schools in Chicago.—The June report of the Chicago Department of Health gives the result of the first year's work in the medical inspection of schools which was instituted September 3, 1896. Of the diseases reported diphtheria was the most prevalent—744 individual reports of cases among school children led to the disclosure of 2619 cases at home. There were 231 school cases of scarlet fever and 745 home cases. Forty-six reported cases of measles led to the discovery of an epidemic prevalence of this disease in several sections of the city during November, 1896, and again in May and June, 1897. In October an epidemic of impetigo contagiosa spread through seven schools of the north division of the city, but was arrested in a few weeks, after excluding 107 cases from the schools and instituting proper preventive measures. Two schools were found afflicted with pediculosis to such an extent as to demand radical treatment. One case of tuberculosis was found at school in such an advanced stage as to justify exclusion from school attendance; this patient died before the close of the school year.

Decision of New York Court against a Doctor.—Forty-four dollars and fifty cents for medical services was sought to be collected, as upon an "account stated," in the case of Callahan against (Margaret) O'Rourke. The evidence for the plaintiff was: That he rendered services as a doctor for the defendant's husband in his lifetime. That, upon one of his calls, defendant's husband paid him \$1. After the husband's death, the doctor presented his bill for such services to the defendant. She paid him \$5, and offered to pay him \$20 in settlement of the bill, saying to him that he had better take \$20 or nothing. No evidence was given upon the part of the defendant. The justice rendered judgment in favor of the doctor. The defendant appealed to the county court, which affirmed the justice's judgment. Thence she appealed to the Appellate Division of the Supreme Court of New York, which latter reversed the judgments of the courts below, with costs and disbursements in those courts, May 26, 1897. It holds that the facts proved were not, under the circumstances, sufficient to establish an account stated between the parties. The doctor's own evidence showed that all the services rendered by him were for the defendant's husband personally. There was no pretense that the defendant ever employed him, or in any way suggested or requested that he attend her husband. There were never any dealings between the plaintiff (doctor) and defendant prior to her husband's death. Under such circumstances, the Appellate Court declares that there was no legal or equitable claim upon the defendant by the plaintiff, and that for that reason there was nothing upon which an account could be stated. Hence the reversal of judgments.

CORRESPONDENCE.

A REVIEWER CRITICISED.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS for June 26, 1897, the very pleasant review of my book is ended by a misstatement which, in justice to my publishers, I feel bound to correct. The reviewer refers to the lithographic plates as "not being comparable to the originals from which they were borrowed." As all of the plates referred to are themselves originals, the reviewer must, I think, be endowed with a curious second sight or double vision, since he is able to compare my plates and their non-existent "originals," so much to the detriment of the former.

This is not the first time that I have known such a statement to be manufactured out of whole cloth, but I hope that, in your journal, it may be the last.

Yours truly,

RICHARD C. CABOT.

BOSTON, July 8, 1897.

[The reviewer of Dr. Cabot's book regrets extremely that he has cast this undeserved reflection upon the plates in question. The idea he had in mind would have been more correctly expressed by the word "modeled" than by the word "borrowed."—EDITOR.]

OXYTUBERCULIN AS A SPECIFIC IN TUBERCULOSIS.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Referring to the leading article in your issue of the 3d inst., "The Treatment of Pulmonary Tuberculosis," by Joseph O. Hirschfelder, M.D., I cannot consider the same of much scientific value as a new discovery, as some investigations of utmost importance have either been forgotten by the author, or else have not seemed to him of sufficient weight to be discussed in his article. Such important questions as the following have not been answered by the writer, viz.:

First. Is the entrance of air into the peritoneal cavity the cause of recovery in cases of peritoneal tuberculosis subjected to laparotomy? Cases cited by the author are so few and inconclusive that we are unable to judge as to the cause of recovery.

Second. Does tuberculin oxidize in the presence of air, or is it the nascent oxygen in this weak solution of hydrogen peroxid that causes this oxidation? Furthermore, has any oxidation whatsoever taken place?

No chemic tests have been applied to verify the author's statements that an "oxytuberculin" has been formed. Would it not have been advisable had the author determined the relative reducing or oxidizing powers of the tuberculin before and after treatment with hydrogen peroxid.

Has the "oxytuberculin" greater therapeutic powers than tuberculin itself? No comparative results are at hand; it would decidedly have enhanced the value of this article as an example of scientific research had the author performed comparative results upon guinea-pigs. These

animals, say fifty to one hundred, should have been inoculated with pure cultures of bacillus tuberculosis, and at different stages of the disease tuberculin and "oxy-tuberculin" should have been injected, and by comparing the number of recoveries in each instance, the author might possibly have verified his statements. In absence of such experiments, I cannot regard the article as the result of deep and long-continued scientific research. Oxidation, no doubt, produces a destruction of animal tissue, but this destruction in itself implies a corresponding reducing action; therefore, it might be asked, is there oxidation in the animal body, as a whole, when tissue is destroyed as in tuberculosis, and does the bacillus tuberculosis produce oxidation in its reaction upon animal tissue? Further researches would establish the truth of this hypothesis, or its falsity.

Are toxalbumens oxidized by hydrogen peroxid (one per cent.), in slightly alkalin solution, so as to cause a change in the chemic reaction of the tuberculin?

Finally, is the author justified in using the word "oxytubercutin," without having verified his hypothesis that an oxidation has taken place in the preparation?

This subject is one requiring careful scientific research, and I am skeptical regarding the author's conclusions, for I find he has hardly more than performed a chemical reaction, without balancing his equations.

S. BOOKMAN, PH.D., M.A.,

Acting Associate in Physiological Chemistry, Pathological Institute, State Commission in Lunacy.

NEW YORK, July 15, 1897.

A REPLY TO DR. WOODBRIDGE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the current number of THE MEDICAL NEWS is a communication from Dr. John Eliot Woodbridge, and as he mentions my name, and is inaccurate in some of the statements referring to my recent criticism of the Woodbridge method of treating typhoid fever, I beg space for correction. He refers first to my comparison of his testimonials to "cancer cures, kidney cures," etc. My only reply is to challenge any fair mind to read for himself these testimonials as published in the recent number (July 10th) of the *Journal of the American Medical Association*, Dr. Woodbridge's paper having been read by title at the recent meeting in Philadelphia. These are similar to the testimonials I saw and criticised. I have no "personal abuse for the Doctor," but he has offered *his method* to the profession, and it must stand or fall upon *its merits*.

I protest that I shall not be misrepresented as having "sanctioned" in my paper the use of phenacetin or any coal-tar derivative. Reference to that paper will prove what I said to have been, "*Such preparations as phenacetin, etc., may be used in small doses, but I deprecate most decidedly the use of any of the coal-tar derivatives at any stage of the disease as being too depressant.*" Again, "*I cannot too earnestly condemn the use of the coal-tar derivatives. Their exhibition is fraught with danger, because of their depressant effect on the heart.*"

Now, sir, as Dr. Woodbridge must have read my whole paper, why does he take a part of a sentence and make me "sanction" the use of a remedy by its quotation, when the unqualified condemnation of the whole sentence and the statement in another part of the paper proves beyond doubt that I do not approve of or use phenacetin in the treatment of typhoid fever (see my paper, *Journal of the American Medical Association*, July 3d). I am as earnestly in search of improved methods of treatment in the cure of disease as Dr. Woodbridge, but I must insist that to commend these methods there must be back of them the full appreciation of a rational pathology, not a hobby. Very respectfully yours,

J. N. UPSHUR,

210 W. GRACE ST., RICHMOND, VA., July 24, 1897.

EDUCATION AS A CURE FOR THE SOCIAL EVIL.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: There are optimists and pessimists in medicine. Noah, according to Scripture, applied the most radical antiseptic measures to the Social Evil, and yet the cat came back. Either auto-inoculation is a scientific possibility, or there is a crack in the veracity of the narrative, or the earthen vessels left after the gonococcus and syphilococcus were buried under the sediment of the flood, were contaminated.

There is much to encourage the social reformer in Noah's history. He blew his own horn for one hundred years and made seven converts. One was his own wife, who, perhaps, had reasons of State for her conversion. Here was a chance to save her husband from the perils of strange women. You see, she was acquainted with the old man.

So the new gold cure for the Social Evil is to be EDUCATION. Well! well!! It is like some people, it won't work. Everybody ought to be good; everybody ought to take muscular exercise enough to make a regular and continent life enjoyable. But they don't. Experience, which has boxed the ears of many generations of theoretic kids, shows how knowledge usually tends to increase the power of a bad egg in society. Congress might appropriate fifty millions of dollars as a perpetual endowment for a Social Evil University, and empower County Boards of Health to matriculate therein every frequenter of the brothel. A curriculum broad enough to include *poetry* would only result in stuffing the students as a Thanksgiving turkey is stuffed. No system ever devised by God or man will make thinkers out of the masses; the thinker is a rare bird. This is the core of the apple.

Let me illustrate the etiology and pathology of the Social Evil. It won't do to ignore the commercial basis of the thing. There is a combination of forces and resources to inoculate the land with the social virus for the sake of the almighty dollar. And yet one man at least sees in alcohol the germicide of criminality. Brother, lend us your head so we can butt it against the argument that ten innocent people are murdered by alcohol where one guilty wretch is crucified. If you have Solo-

mon's desire to find wisdom go to the insurance companies. They have it in stock and would not even take a gilt-edged mortgage on a brewery.

The sporting house is controlled by the proprietor for the sake of the money there is in it. He boards and furnishes rooms to his "girls" at so much per week, and then they must rustle for a livelihood. They earn a commission on every bottle of intoxicating liquor they can sell. It is one part of the business to get patrons drunk, and another part of the business is outright robbery. Most of the women engaged in this traffic have been solicited. Cat-like missionary work is done to reach those men in a community who will prove to be good spenders. Wine suppers where naked women dance are often on the program. A naked woman always is a magnet for the average man.

Prostitutes try to be clean, so far as the genitalia are concerned, and every prospective customer must submit to a physical examination. Faith is the substance of things hoped for, the evidence of things not seen, to the men, and they are liable to pay dear for their whistle. Gonorrhea is regarded by "the profession" in the light of vaccination, but syphilis is a terror, and the black sheep of either sex is summarily cast into outer darkness, where there is weeping and wailing and gnashing of teeth.

I once made a list of fifty married men in a Pennsylvania town where a house of prostitution is not tolerated, and compared it with a list of fifty married men in a Montana town. Coffee and whisky are both pernicious stimulants of the nervous system, because there were as many baldheaded and prematurely aged men in one list as in the other. The wives of the Westerners compared favorably with the wives of the Easterners. There were no more stillborn children, premature births, gynecological cases among the former than among the latter. As to fecundity, the Eastern women has a shade the advantage, not enough, however, to prove that interference with conception or the product thereof was more general in one section than in the other. Western children, compared with Eastern children, are the same darlings, mentally and physically, with, perhaps, a streak of irreverence for the Sabbath. Of course, the wives would be pleased to have Providence smite the "social settlement" in Western towns with fire and brimstone, but Providence does not do business in that way.

Our method of dealing with the Social Evil is to fine the women, which amounts to license. The men who patronize the industry ought to be enrolled at the police station and the names periodically advertised in the newspapers just as uncalled-for letters at the post-office are advertised. Law, religion, or medicine furnishes no warrant for dealing with a sinner gently because he is a man. What is sauce for the goose should be sauce for the gander. It is not morally right to deal with the Alcoholic Goliath as with a spoiled child, and then to hand his lusty daughter over to the tender mercies of the medical profession.

JAMES KIRBY FREE.

BILLINGS, MONT., July 10, 1897.

OUR VIENNA LETTER.

[From our Special Correspondent.]

PROSPECTIVE CHANGES IN THE VIENNA GENERAL HOSPITAL—INFLUENZA AS AN ENDEMIC DISEASE AND SOME OF ITS COMPLICATIONS—A SIMPLE MODIFICATION OF COW'S MILK FOR INFANT-FEEDING—CELEBRATION OF PROFESSOR JOSEPH GRUBER'S SEVENTIETH BIRTHDAY—FERIAL COURSES IN VIENNA IN SEPTEMBER.

VIENNA, July 10, 1897.

A RECENT ministerial announcement seems to assure a great change in the *Allgemeines Krankenhaus*, the special medical feature of Vienna. A large part of the old hospital, which has been a familiar landmark since Joseph II.'s time, at the end of the last century, is to be torn down. In its stead a large apartment house is to be erected at the corner of Alser Strasse and Spital Gasse. The gradual increase of traffic around and past this corner, especially since the introduction of the electric tramway, has made it very unsuitable for hospital purposes. Altogether, wards which are capable of accommodating 1000 patients are to be torn down, but wards for 1750 patients are to be furnished in their place by the erection of a series of buildings on the pavilion plan on the grounds of the National Insane Asylum on Lazareth Gasse. The change will be a welcome one, I am sure, to both doctors and patients, and it demonstrates that the government has at last come to realize that if Vienna is to retain the high place she has held in clinical medicine better clinical facilities must be at hand. The old building, while it must have been considered a model hospital in its time, is sadly deficient in most things which are considered indispensable in a modern hospital. Facilities for ventilation, disinfection, and segregation, are of the most primitive kind, and the only places available for microscopic and chemical examinations of blood, secretions, and excretions are in the wards themselves.

The result of this state of affairs was that when the last vacancies occurred in professorships in medicine and surgery men to whom the places were offered would not accept them. Neither Erb nor Maunyn cared to leave their well-appointed clinics at Strasburg and Heidelberg to take the old-fashioned wards in Vienna, despite the magnificent material the clinics afforded and the prestige of the Vienna school. Czerny was of the same mind with regard to the surgical clinic so that the Minister of Public Instruction had to seek farther for candidates for the vacant chairs. With the new order of things this is not so likely to happen unless the short-sighted pecuniary policy of the Austrian government should stand in the way.

That influenza has again become endemic in most of the countries of Europe seems clear. Cases in which Pfeiffer's bacillus can be demonstrated in the sputum are nearly always under treatment in the various hospitals of Vienna. Irregular, severe bronchitides, with a tendency to bronchopneumonia, lobar pneumonia running a peculiar course, and complicated with symptoms of great depression, heart disturbance, and the involvement of other mucous membranes besides the respiratory tract are almost invariably suspected as of grippal origin, and the

bacillus can nearly always be demonstrated without trouble. The well known tendency to mixed infection, so readily explicable now that it is known that Pfeiffer's bacillus is preferably symbiotic even in ordinary culture media, and grows more luxuriously where other micro-organisms are present, is looked upon clinically as almost pathognomonic. Occasionally cases are reported from the hospitals where, among weakened patients, the disease seems to be communicated to one or more in a ward, so that in its occasional occurrence in an endemic form it has not lost entirely the contagious character of its epidemicity.

The *post-mortem*-room makes some interesting revelations as to the fatal character of the complications and sequelæ of the disease. Many of the fatal cases occur as the result of the infection during the winter epidemic here and they form a very striking commentary on the serious nature of the disease, to which, when it first became epidemic, it was the custom to refer so jokingly. Putrid bronchitis, gangrene, and abscess of the lungs, the origin of the process being an influenzal pneumonia months before, without tendency to complete resolution, are not by any means a rare find on the autopsy-table. Still more striking are the nervous and vascular affections of which the most probable etiology seems to have been the toxins of the influenza bacillus. Myelitis, polyneuritis, in the form of an ascending paralysis (what would be called "Landry's paralysis," I suppose, if the cause were not known), and muscular atrophy have been noted. Pathologic changes are found in the intima of arteries, a toxic influenzal endarteritis which seems to account for bleedings from the mucous membranes of the nose, mouth, uterus, etc., and hemorrhages in the skin. The formation of marantic thrombi from toxic disturbance of the nervous heart mechanism, with lung emboli and sudden death also is common, some of the cases looking very like the sudden deaths which, without autopsy, go to swell our health-board reports of heart failure. The more one sees of it the more one realizes how little is really known of the disease and its varied possibilities.

One of the large dairy companies which supplies Vienna with milk furnishes families at a very reasonable rate with a modification of cow's milk which represents mother's milk very closely in its composition, and gives excellent results in infant-feeding. The formula employed is a modification of the method of preparing cow's milk suggested by Vigier some three years ago, which is now used, with slight modifications, in a good many places in Europe. A half liter of milk is treated with lab-ferment and then filtered through silk. The resulting liquid, which contains about one per cent. of albumin in solution, one per cent. of fat, and $5\frac{1}{2}$ per cent. of sugar, is added to a half liter of good rich, full milk. The whole is then pasteurized and distributed in sealed glass flasks.

The method of preparation is an easy and very adaptable one, and the absence of chemic manipulation commends it. It may easily be modified to suit varying conditions in the child, or to meet the necessity for more nutritious food as the child grows older; in fact, the company supplies two or three modifications according to the

wants of its patrons. The results reported from the use of this "Sangling's milch" are very encouraging. Especially does it commend itself in the cases of weak, delicate children. At the Polyclinic, in the hospital itself, and in the Out-patient department, it has given better results than anything so far tried.

Many American physicians who have studied in Vienna will be interested in the announcement that the seventieth birthday anniversary of Professor Joseph Gruber, the distinguished otologist, occurs this year, and that his many friends and pupils have resolved to celebrate it fittingly. An international committee is being organized, and the details of the celebration are being arranged. The birthday occurs in August, but as this is vacation time the celebration is to take place in October. A bronze medal bearing an image of Professor Gruber is to be struck in honor of the occasion, and is to be a souvenir for those who take part in it.

The programme of the Ferial courses for August and September is just out. They are no longer an experiment but are evidently meant to rival the corresponding courses given at Berlin which have deservedly been so popular. The courses announced for September are especially good, notably in pathology and some of the specialties. Visitors on the way home from the Congress at Moscow will thus have an opportunity to study the methods of the Vienna school.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Third Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1897.

The President, FRANK HYATT, M.D., of Washington, D. C., in the Chair.

THE proceedings were opened by an address from the President. He touched upon some of the more noteworthy achievements during the past year in the branches of medicine coming within the scope of the Society. In the recent congress, he said, seventy-five per cent. of the papers had been devoted to rhinology. An especially interesting contribution was one on ozena, in which it was claimed that a large percentage of the cases of this disease could be cured by the application of the electric current—twenty milliampères for twenty minutes at a time. In the Vienna Congress the prevailing sentiment was opposed to the radical surgical procedures which had been advised in Germany, especially in the treatment of antrum disease. It was also agreed that too much stress had been laid upon the teeth as a cause of such disease. The accessory cavities were discussed also, before the British Society of Laryngology, Otology, and Rhinology. Here it was stated emphatically that operations in frontal empyema should not be considered successful unless drainage was provided through the nose. The ethmoid cells had been discussed in three scientific papers. Mackenzie had brought forward proof of the incorrectness of the statement that suppurative inflammation of the ethmoid has a tendency toward producing necrosis. He

also said that there was no special tendency in these cavities to myxomatous degeneration. A number of authors had called attention to the lingual tonsil during the past year, and had spoken of the significance of its pathologic lesions. Lennox Browne, in 1547 cases of nose and throat disease, had found the lingual tonsil varicose in 438, and in thirty-seven per cent. of these there was also hypertrophy of the gland. MacIntyre had made a report bearing upon the value of the X-rays in investigating diseased conditions of the nose and throat.

There had also been commendable activity in the practice of otology during the past year. The importance of asepsis in connection with the ear had been strongly urged, and cerebellar abscess had been made the subject of many important contributions. In mastoid operations, it had been found that the best results followed frequent dressings.

CHRONIC NON-SUPPURATIVE OTITIS MEDIA

was the title of a paper which was then read by DR. S. MACCUEN SMITH of Philadelphia. He said that the nasopharynx necessarily must be considered in this connection because of its important etiologic relations to the subject under consideration. For clinical purposes it is sufficient to regard the several varieties as different stages of one disorder, beginning with a simple catarrh and ending with advanced trophic changes involving the internal ear, and attended by deafness and tinnitus. The author did not believe that the general health of the patient had any material influence on the development of the disease except in the case of syphilis. The true underlying condition is a catarrh of the nasopharynx. There will be found more or less obstruction of the Eustachian tube, marked retraction of the membrana tympani, with thickening, displacement of the ossicles, and the whole bound down by firm adhesions to the promontory. If, in addition, there is impaction or bony union of the stapes to the foramen ovale, it is not at all wonderful that efforts toward relief meet with comparatively little success. Not only must the catarrhal condition of the nose and throat be controlled, but the free nasal respiration must be established. It seems foolish to hope for relief in cases of ankylosis and adhesions without first securing liberation of the membrana tympani and ossicles.

The treatment should consist of an incision into the membrana tympani along the entire length of the handle of the malleus. Through this a small knife should be introduced, and the adhesions divided. With a small hook, efforts should be made to break up the adhesions. A few drops of sterilized albolene should then be instilled into the tympanic cavity. The canal should be filled with iodoform gauze, care being taken that it does not impinge on the membrana tympani. The gauze should be removed on the third or fourth day. Massage of the ossicles at intervals of three or four days is next in order. In the experience of the writer, additional injections of oil can be made into the drum-head. From ten to twenty hypodermic injections of the hydrochlorate of pilocarpin, at intervals of two or three days, may be given with advantage. Phosphorus and strychnin should be administered

internally. Of course, the nasopharynx should have received proper attention before this line of treatment is begun.

DR. CHARLES W. RICHARDSON of Washington, D. C., reported a case of

LARYNGECTOMY FOR MALIGNANT DISEASE OF THE LARYNX.

During April, 1896, he had been asked by Dr. Butler to see a well-nourished man who had a red growth, about one centimeter in diameter, which sprung from the left wall of the larynx just above the cord. There was a good family history and no evidence of syphilitic taint. Examination of the growth, after removal, showed it to be an epithelioma. At the time of the operation last December the patient's general condition was bad, and cancerous cachexia was marked. He suffered from paroxysms of severe dyspnea, and could sleep and eat but little. There was no pain in the laryngeal region, or any pain of a reflected character at any time. There was no infiltration or involvement of neighboring glands. Both cords had been destroyed, and their places were occupied by nodular new growths of a whitish appearance.

On December 12, 1896, a preliminary, low tracheotomy was performed. On December 19th, laryngectomy was performed, the operator using Gerster's tampon canula. During the operation some trouble was experienced from profuse hemorrhage, owing to the accidental division of a deep vein. The upper end of the esophagus was stitched subcutaneously to the upper end of the transverse wound so as to completely shut off the pharyngeal cavity. The epiglottis was left *in situ*. During the first day after the operation the patient seemed much more comfortable, and his temperature was 99° F. On the evening of the second day, he suddenly became much worse and died shortly afterward from acute edema of the lungs.

Examination of the larynx after the operation showed that the extent of the growth was far greater than had been supposed, as it filled the whole interior of the larynx and even extended into the trachea. It seemed to the speaker that it is more properly surgical to unite the flaps and close the wound than to follow the usual plan of using gauze packing.

PAPILLOMA OF THE LARYNX RECURRING AS AN EPITHELIOMA.

DR. M. R. WARD of Pittsburg, Pa., read a paper with this title. He reported the case of a girl, seventeen years of age, with a family history which was negative as regards carcinoma. During 1893 she had had an attack of epidemic influenza, and soon after had noticed that she was hoarse and could not speak above a whisper. On consulting a physician, she was told that there was a growth on the vocal cord. During July of the same year the growth was removed by Dr. Day of Pittsburg. He considered the growth to be a papilloma, and the examination of the pathologist confirmed the diagnosis. The patient gradually grew worse until November, 1895, at which time Dr. Ward first saw her. The arytenoids were freely movable, and the anterior half of the left vocal cord was almost completely destroyed by ulceration. The

ulcer was ragged and irregular, and surrounding it was an infiltration of the submucous tissue. The right vocal cord was congested and swollen, and the chink of the glottis was much narrowed.

Tuberculosis was excluded by physical and microscopic examination. The girl was given mercurial inunctions and increasing doses of iodid of potash, and at the same time a spray of absolute alcohol was applied to the larynx in the hope that the growth might prove to be papillomatous. She steadily became worse in spite of the spraying, so one month later a tracheotomy became necessary. At this time the anterior two-thirds of the left vocal cord was totally destroyed, and there were numerous irregular nodular masses of bright red, diseased tissue on the left side. There was no enlargement of the cervical glands. On March 14, 1896, laryngotomy was performed. Numerous masses were found beneath the vocal cords, and were removed. The laryngeal cartilages were apparently healthy. During the first twenty-four hours the wound was left open and was packed with iodoform gauze.

The specimen removed from the larynx was examined by Dr. Wasden, and found to be a mixed epithelial growth—an adeno-epithelioma. The disease soon showed evidence of recurrence, and a laryngectomy was then performed. At this time there was no recognizable lymphatic involvement. The entire larynx, epiglottis, and a portion of the anterior wall of the esophagus were removed. The patient was nourished through an esophageal tube. The wound healed readily and convalescence was uncomplicated. About August 8th, a recurrence was noted, and on October 25th the patient died of exhaustion, almost three years after the disease was first recognized.

The case is of interest, not only on account of the unusual situation of the growth, and the comparative youth of the patient, but because the evidence that the growth was originally benign was exceptionally strong. Dr. Delavan recently had stated that the etiology of laryngeal cancer is as little understood as that of cancer occurring in other parts of the body. The solution of the question can only be made by an appeal to statistics. The investigation of this subject undertaken by Semon still maintains its position as being decidedly the most valuable contribution to our knowledge. These statistics are as follows: Number of benign tumors observed, 10,747; number of papillomata, 4190; number of intralaryngeal operations on benign tumors, 8216; number of intralaryngeal operations on papillomata, 3382; number of repeated removal, 480; number of spontaneous degeneration, 12; number of degeneration after intralaryngeal operation, 31. The speaker said that the most formidable stumbling-block lies in the difficulty in making a positive diagnosis between papilloma and a carcinoma in the early stages. Clinically, this is often impossible, and even the microscope has not always yielded trustworthy results.

DR. JAMES KERR of Washington, D. C., reported a case of

He had been asked by Dr. Hyatt to see the patient with reference to the advisability of performing tracheotomy. This was performed about one month before the laryngectomy. The points which decided them in favor of the operation in the case were: (1) The stronger probability of the growth being a carcinoma; (2) the growth was distinctly confined to one side of the larynx; (3) there was no involvement of the lymphatic glands, or of the tissues outside of the larynx. The patient was a woman, fifty-four years of age, who had long been in poor health, and whose kidneys were inactive. The daily quantity of urea did not rise above 180 grains, and was often much less. In addition to this, the heart action and digestion were poor, and she was quite neurotic. It was hoped that a partial laryngectomy would be sufficient—a much less dangerous operation than complete laryngectomy.

The operation itself presented no special difficulties. The cricoid cartilage was split behind, and the larynx was then separated from the esophagus and the cricothyroid membrane divided. On opening the larynx it was found that the growth completely blocked the larynx, but it was quite adherent on the right side. Throughout the operation there was practically no hemorrhage. The patient's strength had been fortified prior to the operation by the administration of strychnin and atropin, and she had been given saline enemata. At the time of the operation the head was placed lower than the body. This also had the advantage of guarding against lung infection by keeping the blood out of the trachea. At the close of the operation the patient's general condition was exceedingly satisfactory. Instead of using the balloon tampon-cannula of Trendelenburg, a piece of compressed sponge was substituted, and as soon as it became moistened with the secretions it swelled and tightly closed the opening. This device acted admirably. Rectal enemata were employed during the first three days, and then she was able to eat small pieces of meat. The patient did very well at first, and although there was no evidence of septic pneumonia or other complication directly connected with the operation, her strength gradually failed and she succumbed at the end of the first week. Dr. Reed of the Army Medical Museum at first looked upon the case as one of epithelioma, but further examination led him to believe that it was a medullary carcinoma originating in some of the glands of the mucous membrane of the larynx.

TRACHEAL INJECTIONS IN THE TREATMENT OF LARYNGEAL AND PULMONARY INFLAMMATIONS.

DR. JOHN A. THOMPSON of Cincinnati, Ohio, read a paper with this title. He said that by intratracheal injections one obtains the direct action of the remedy on the diseased area. There are many proofs that tracheal injections are speedily absorbed. The cure of a bronchitis by such direct medication, without interfering with digestion or appetite, is a distinct advance in therapeutics. In tuberculosis there is a mixed infection—a secondary infection with the germs of suppuration. A little menthol injected into the trachea will give greater and more prolonged relief than a large dose of morphin given by the

mouth. The remedies should be soluble in the vehicle employed, the solutions should not be very irritating, and the drugs so used should be capable of volatilizing slowly at the temperature of the body.

The speaker said that he had first become convinced of the great value of this method of treatment by observing its excellent results in pulmonary tuberculosis and chronic bronchitis. When the remedies are not irritating, it is not necessary to use cocain previously. He uses from one to four drams of a solution at a sitting, and ordinarily there is little coughing or strangling.

DR. J. E. NICHOLS of New York presented and demonstrated the action of a new electric-lighted aural speculum. It consists of a double speculum, the upper part of which contains an electric lamp, and the lower part the illuminating apparatus. A diaphragm extends half-way through the lumen of the speculum. The back of the lamp is covered by a polished mirror. The reflection from the electric light is thrown directly from the end of the speculum, and is focused upon the membrana tympani. The instrument can be adjusted to the head of the patient without difficulty. This allows the operator to use both hands.

DR. SCHREPPEGRELL of New Orleans, La., exhibited a new mechanical saw and masseur. In this instrument the handle, instead of being at right angles with the direction of the saw, is placed at an obtuse angle, thus giving it the shape which has been found the most convenient in ordinary nasal saws, and which prevents the hand which holds it from coming too near the face of the patient. In order to permit this position, the backward and forward movement of the saw is obtained by means of a ball revolving in an eccentric. The saw is operated by the ordinary motor or dental engine.

VIBRATION FIGURES PRODUCED BY THE HUMAN VOICE.

DR. H. HOLBROOK CURTIS of New York said that Messrs. Watts and Hughes of London in 1885 first made experiments having for their object the demonstration of the vibrations of the human voice on stretched membranes. Fanciful figures were made in this way, not only with powders, but with pigments. These pigments will shoot out and interlace and produce the most beautiful flower-like forms with variations of color. By using a square instead of a circular bowl for the membrane, the serpent forms were produced.

He presented pictures illustrating what he had accomplished in this direction. He has discovered that under certain conditions of tension and a certain specific gravity of a salt and emery mixture each note of the singing voice produces a certain definite geometric figure. Slight variations in *timbre* and overtones will produce slight variations in the figures without altering their form. In explaining the apparatus, he said that it took weeks to get the india-rubber diaphragm in a condition to respond delicately to the notes produced. Equal tension can be secured only by marking a small circle on the rubber, and then by stretching the rubber in accordance with this outline. After having done this, the rubber each day, or oftener, should be excited to vibration by gently tapping

or rubbing it to render it homogeneous. The pictures were as exact representations of pitch as are the responding notes of different tuning-forks or resonators. By means of a series of photographs of these figures, the speaker pointed out the relationship between the various tones and the construction of a chromatic scale in geometric tone-figures of great intricacy and beauty.

LABYRINTHIN PHENOMENA DEPENDENT UPON MIDDLE EAR DISEASE, AND THEIR RELIEF BY LOCAL TREATMENT

was the title of a paper by DR. EDWARD B. DENCH of New York. He said that in this class of cases physical examination will reveal a considerable retraction of the drum membrane, and sometimes slight congestion of the manubrial and peripheral plexuses. The caliber of the Eustachian tube is slightly reduced, the air entering the tympanum on catheterization but producing a rough sound indicative of thick mucus adherent to the walls of the canal. Quite frequently inflation causes a moderate amount of vertigo. There often is slight temporary improvement after the inflation, lasting a few hours. The rarefaction of the air in the middle ear, caused by the narrowing of the Eustachian tube walls, produces a condition similar to that seen in cases of labyrinthin concussion. The ossicular chain is displaced inward, with considerable force, and the stapedius and tensor tympani muscles are unable to protect the labyrinth from the sudden increase in tension, the result naturally is concussion. This condition is most frequently found in neurotic persons. The fact that the functional examination shows no interference with sound conduction does not affect the value of this examination; it points out a hyperesthetic condition of the perceptive apparatus. Treatment should be instituted early. These cases will often prove misleading unless the appearance of the drum membrane, the condition of the Eustachian tube, the history of the case, and the result of the functional examination are all considered.

DR. SARGENT F. SNOW of Syracuse, N. Y., then read a paper, entitled

HEADACHES FROM NASAL CAUSES.

This has been published in a recent number of THE MEDICAL NEWS.

THE CURE OF SINGER'S NODULES.

DR. HOLBROOK CURTIS of New York read a paper with this title. He said that a singer's nodule is an inflammatory growth situated at the junction of the anterior and middle-third of the vocal cords. These nodules are due to an improper method of attacking tones, or to using a focus of tone in such a way that attrition becomes possible. The damage occurs chiefly in singing the upper medium register. That they are not true nodes, in an acoustic sense, but the result of attrition, has been demonstrated by investigations with the stroboscope. In examining these cases, the patient should be directed to talk, and not to sing, repeating the sound of A. While holding the tongue with a tongue depressor, the patient is next directed to change to E. This shows the cords in their anterior position without strain or undue tension.

One of the first symptoms of singer's nodules is that the singer's voice becomes hoarse after singing. They do not necessarily result from overwork or from a cold. In opera singers he had frequently noticed nodules appear in a single night as the result of a change from one language to another. In the acute cases, the necessary exercises for relief should be begun immediately. By a proper use of gymnastic exercises of the intrinsic muscles of the larynx the singer is put at once into a condition for singing. The object of the treatment is to make the cords adopt a new method of vibration. That the cords by an alteration in the overtones really adopt a new segmentation, and that this prevents further attrition has been demonstrated by the repeated cure of nodules by no other means than a change of method in singing. A number of cases were cited and illustrated by means of pictures of the cords at various stages of treatment.

Simple exercises in singing which he had devised represent fifteen years of study of tone production. The accessory cavities of the face are the normal resonators of the human voice. It is very important that patients should not be allowed to talk during the treatment for they talk in the medium register, and hence aggravate the trouble. Respiration is an important factor. The patient should be made to maintain a raised chest during the exercises, not by a respiratory, but purely by a muscular effort. By cultivating these exercises the breathing will become purely diaphragmatic, the size of the chest at the lungapices will be increased, and the *timbre* of the voice improved.

SARCOMA OF THE LARYNX—SARCOMA OF THE NASOPHARYNX IN AN INFANT.

DR. T. H. HALSTED of Syracuse, N. Y., reported these cases. He said that the disease is now a rare one, yet he felt sure that owing to the fact that unsuccessful operative cases are not often reported, the condition is not as rare as statistics would seem to indicate. His two cases—the only ones of the kind he has seen—had come under observation during the past year.

CASE I.—J. H., male, fifty-seven years of age, came to him on June 11, 1896. There was difficulty experienced in swallowing just as the food reached a point opposite the larynx. A constant, ropy secretion was expelled by coughing, and there was an excessive secretion of saliva. The laryngoscope showed the presence of a rounded, grayish, non-ulcerating sessile tumor, about the size of a walnut. On June 17th, the tumor was removed in four pieces by the cold snare. It was examined and reported to be a large, round-celled sarcoma. The patient did not return until July 17th, and then it was found that the growth had recurred, and was larger than at the time of the operation. Partial laryngectomy was offered as the only chance, but the patient did not appear again for six months. At that time he had severe paroxysms of dyspnea, particularly at night, and leaning forward at any time excited great difficulty in breathing. He had lost flesh. The tumor filled the larynx, and the vocal cords could not be seen.

On January 29, a tracheotomy was performed because of an exceedingly bad attack of dyspnea. A week later, the growth appeared at the opening in the trachea. After

another week it had reached to the base of the tongue. During these two weeks he was more comfortable than before the tracheotomy, but his general condition did not improve. He died on April 27th. During six weeks prior to death a large part of the fluid food taken was regurgitated. The cough was a constant and distressing symptom but codein was very effective in controlling it. There was slight hemorrhage at times, and on one or two occasions it became very profuse.

CASE II.—A child of two years in whom the respirations were labored, noisy, and rapid, had marked cyanosis. She was dull and only partially conscious. The right side of the nose was occluded by a yellowish-white growth and the soft palate was pushed forward by another mass. The attending physician had first seen the child twenty-three days before. The symptoms had developed at a time when the child was in the neighborhood of a number of children suffering from a catarrhal affection. Tracheotomy was performed, as the mother insisted upon the institution of some measure for the child's immediate relief, but it died shortly afterward. The growth proved to be a sarcoma.

THE SURGERY OF THE FAUCIAL TONSIL

was the title of a paper by DR. G. HUDSON MAKUEN of Philadelphia, Pa. He said that two conditions of the tonsil should be considered as pathologic: (1) The hypertrophied condition so common in children; and (2) the later stage of this, known as the atrophied condition. The faucial tonsil, no matter how large, does not, as a rule, interfere with the breathing except when the vault of the pharynx also is obstructed, but the enlarged tonsil acts unfavorably on the surrounding tissues, irritating the parts and causing congestion and hypersecretion. The adhesions often cause the formation of a pocket, in which the secretions collect and decompose, and, perhaps, finally burrow into the tissues, giving rise to a tonsillar or peritonsillar abscess. The atrophied tonsil is as prejudicial to health as is the hypertrophied tonsil. All measures not surgical are only slightly palliative. The indications are to reduce the size of the mass, and to favor cleanliness by removing the pockets or crypts.

The speaker uses a blunt hook for diagnostic purposes, and a cutting hook for separating the adhesions. After such operations the raw surfaces should be seared with the cautery, and the parts should then be sprayed with peroxid of hydrogen, and anointed with liquid albolene. By such precautions the patient rarely suffers from the operation. If the tonsils project beyond the pillars they should be removed, either by the tonsillotome or by means of knives. A method which he has found very useful in adults is the opening up of the crypts at repeated sittings, and so gradually removing the redundant portions of the tonsil.

PRIMARY SYPHILITIC INFECTION OF THE TONSIL.

DR. ARTHUR G. ROOT of Albany, N. Y., reported the case of a man who had had the usual diseases of childhood, and had had reasonably good health up to the time of an attack of gonorrheal rheumatism during the spring of 1894. This attack lasted for four months.

During March and April, 1896, the patient contracted a cold, which affected the tonsil. The next month the same tonsil again troubled him, and it became painful and inflamed in June. At this time he noticed a few blotches on the abdomen. When seen, two weeks later, the tonsil was the seat of a grayish ulcer, and the submaxillary and cervical glands were enlarged. The patient was given protiodid of mercury, and saturated solution of iodid of potassium internally three times a day, and his diet and habits were regulated. The throat has been kept in good condition by local applications, and at the present time, the local and general conditions are good.

In commenting upon the case the speaker said that after a careful investigation of the patient and of his mistress, he had come to the conclusion that the lesion was probably the result of kissing the girl who was syphilitic, and that the infective agent had gained entrance owing to the inflamed condition of the tonsil.

THE TREATMENT OF SUPPURATIVE DISEASES OF THE ACCESSORY SINUSES AND OF THE EAR BY OZONE GAS

was the title of a paper read by DR. W. SCHREPPEGRELL of New Orleans, La. The speaker had made a number of experiments to test the efficiency of oxygen gas, as recommended by Dr. Geo. Stoker. His results, however, had been unsatisfactory, as oxygen is an inert gas. Nascent oxygen, however, is an active oxidizing agent, and he has found it useful in these cases. He obtains this from ozone, which is an allotropic form of oxygen.

After referring to the various methods of generating ozone, he described a method which he has found the most practicable. A Siemens' ozonizer, which is connected with the terminals of a strong induction coil, is used, those employed for the production of X-rays being useful for this purpose. The air from the compressed-air apparatus is passed through this ozonizer, and a certain percentage of oxygen is changed into ozone, which is carried directly to the diseased parts by means of a rubber tube, and the proper canula for the diseased cavity. Photographs were shown illustrating this method.

The nitrogen products in this method are so infinitesimal that they may be neglected. For the patient's use at home, ozone may be prepared from a solution of diluted hydrogen dioxid acidulated with sulphuric acid to which one-grain tablets of permanganate of potash are added.

In using the ozone, the valve, which is controlled by the patient, is opened only during expiration so that the patient does not inhale the gas. No bad effects have been complained of by the patients upon whom this method has been used. The speaker reported the effects of this treatment in a case of chronic antral disease, a case of combined empyema of the frontal and maxillary sinuses, three cases of chronic otitis media, and two cases of ozena. The good effects were remarkable. The bacteriologic investigation showed the marked microbicidal effects of ozone. The method is simple and promises to be a useful one in the treatment of chronic suppurative processes and in ozena.

REPORT OF A CASE OF ABSCESS OF THE NASAL SEPTUM.

DR. L. C. CLINE of Indianapolis, Ind., reported the case of a girl aged twelve years who had been treated for a mucopurulent discharge from the nostril. Some months later she fell and struck her nose. There was considerable pain and hemorrhage, and an irregular practitioner being called in, he diagnosed typhoid fever, and proceeded to treat her for that disease. When Dr. Cline saw her there was an abscess of the nasal septum with marked displacement and injury to the bony structures. The case was one of septic fever, due to traumatism, and it emphasizes the necessity for more attention being given to these seemingly trivial injuries to the nose.

DR. C. A. THIGPEN of Montgomery, Ala., reported several cases of

OTITIC BRAIN DISEASE

following attacks of *grippe*, and DR. W. SCOTT RENNER of Buffalo, N. Y., read a paper on

CHRONIC FOLLICULAR TONSILLITIS.

DR. EWING W. DAY of Pittsburg, Pa., followed with a report of a case of

OTITIS MEDIA, WITH THROMBOSIS OF THE SINUS AND JUGULAR VEINS,

after which the Society adjourned.

REVIEWS.

DISEASES OF THE EYE AND OPHTHALMOSCOPY. A HAND-BOOK FOR PHYSICIANS AND STUDENTS. By DR. A. EUGEN FICK, University of Zürich. Authorized translation by ALBERT B. HALE, A.B., M.D., one of the Ophthalmic Surgeons to the United Hebrew Charities; Consulting Ophthalmic Surgeon to Charity Hospital, Chicago. With a glossary and 158 illustrations. Philadelphia: P. Blakiston, Son & Co., 1896.

APPEARING, as it does, so soon after Fuchs' masterly work, the Zürich professor's text-book suffers but little by comparison; in fact, many chapters, especially those on functional tests and on physiologic optics, are excellent. As much cannot be said for the sections devoted to clinical pathology and treatment, where a certain irregularity and lack of cohesion are manifested. There are a number of omissions. The subject of injuries of the optic nerve is passed over, while retinal shock (*commotio retinae*) is presented in detail. In fact, the chapters on injuries are particularly complete.

The translator's work has been, in the main, well done. His English is generally clear, concise, and a faithful rendition of the author's thought. In many places, however, it is too literal, or awkward, and the reverse of idiomatic. We cite as instances: "A whole row of tonometers have been thought out," "eyes red wept," and the inaccurate translation of "eut stillung" (disfigurement) by "displacement" (p. 154), of "Krebs auge" (eye-stone) by "crab's-eye."

The glossary (Appendix B), containing etymologies from Gould's Illustrated Medical Dictionary, Second

Edition, is full of inaccuracies, ambiguity, and pseudo-philology. Lest this criticism may seem unduly harsh, the following instructive examples are given: Acne (*αχνη*, a point), a disease of the sebaceous glands. This definition certainly misses the point entirely; chemosis (*χημωσις*, a gaping); epiphora (*ἐπι*, on; *φερειν*, to bear); gerontoxicon (*σίζ*), arcus senilis; hippus (*ἵππος*, the horse), spasmodic pupillary movements, independent of the action of light, natural in the horse. This is a startling discovery in equine physiology as well as in philology! For condensed misinformation we must, however, award the palm to kargokinesis, which is from *κάρνον*, a rent (nucleus); and *κίνησις*, change, and signifies *changes accompanying maturation of the ovum*! Almost on a par with this brilliant definition is that of *κόρη*, the pupil of the eye, so called, like the Latin pupilla, because an image appears in the eye.

The general appearance of the book reflects no little credit on the publishers. The typography is excellent and the illustrations are unusually well chosen and admirably reproduced.

ANOMALIES AND CURIOSITIES OF MEDICINE: Being an Encyclopedic Collection of Rare and Extraordinary Cases, and of the Most Striking Instances of Abnormality in All Branches of Medicine and Surgery, Derived from an Exhaustive Research of Medical Literature from its Origin to the Present Day, Abstracted, Classified, Annotated, and Indexed. By GEORGE M. GOULD, A.M., M.D., and WALTER L. PYLE, A.M., M.D. Imperial octavo, 968 pages, with 295 illustrations in the text, and 12 half-tone and colored plates. Sold only by subscription. Philadelphia: W. B. Saunders, 925 Walnut street, 1897.

Few men are possessed of that order of mind which finds congenial work in the construction of a volume like the above, and yet the man who does such work is placing the profession under obligation in that he renders one more department of information easily accessible. The work, of course, is designed solely as a book of reference, and is in itself a curiosity. He who consults this book for a brief hour is again reminded that facts are stranger than fiction. The question of credibility in regard to the remarkable statements made and cases reported is discussed by the authors in the preface, and they hasten to disavow any responsibility for the truthfulness of the chronicles given. The material is conveniently classified and arranged, and there is an elaborate table of contents and a carefully prepared general and bibliographic index.

GUY'S HOSPITAL REPORTS, Vol. LI., being Vol. XXXVII. of the third series. Edited by E. C. PERRY, M.D., and W. H. A. JACOBSON, M. A. London: J. & A. Churchill, Great Marlborough Street, 1896.

THIS volume appears in its usual form, and contains a number of valuable articles from the pens of the visiting lecturers and surgeons. The first one hundred pages are occupied with the memorial sketch of Arthur Edward Durham, by W. H. A. Jacobson. The volume also contains an admirable portrait of the subject of this sketch.

LECTURES ON THE TREATMENT OF FIBROID TUMORS OF THE UTERUS, MEDICAL, ELECTRICAL, AND SURGICAL. By FRANKLIN H. MARTIN, M.D., Professor of Gynecology in the Post-Graduate Medical School, Chicago; Surgeon to the Woman's Hospital, etc. Chicago: The W. T. Keener Co., 1897.

IN this short sketch, Dr. Martin has given a mirror of the status of the consideration of fibroid tumors of the uterus. His conclusions are, in the main, conservative. He advocates the medical and electrical treatment of these neoplasms only when a surgical operation is refused, or is impossible or inexpedient. The historic sketch accompanying each chapter adds to the value of this little work, which is modern and certainly worth reading. The various operations for uterine fibroids are particularly well discussed. The illustrations are, on the contrary, quite crude, and the proof-reading has not been well done.

ATLAS UND GRUNDRISS DER LEHRE VOM GEBURTS-AKT UND DER OPERATIVEN GEBURTSHILFE. VON DR. OSKAR SCHÄFFER. Fourth edition. Munich: J. F. Lehmann, 1897.

THAT a fourth edition of this excellent atlas of the obstetric mechanism and of operative obstetrics has been called for, is sufficient evidence of its worth. No changes have been made since the last edition, nor, indeed, are any called for. The text has been somewhat elaborated, but the splendid drawings remain as they were. Except for work on the phantom, we know of no more graphic method of teaching obstetrics theoretically than by the aid of Schäffer's atlas.

LECTURES ON RENAL AND URINARY DISEASES. By ROBERT SAUNDBY, M.D., Fellow of the Royal College of Physicians, London; Emeritus Senior President of the Royal Medical Society, etc. Second edition. Illustrated. Philadelphia: W. B. Saunders, 1897.

THE author's wide reputation as a clinician makes it not surprising that a second edition of his well-known lectures on urinary diseases should be demanded. The present edition contains many emendations and additions, and a chapter has been added on the miscellaneous diseases of the kidney, giving the work more of the character of a reference-book.

The first section deals fully with Bright's disease, considered in its anatomic, etiologic, and clinical aspects, together with its complications. The pathology of uremia and a consideration of infective, lithemic, and obstructive nephritis, with their treatment, complete the first part of the book.

The second section contains thirty-nine pages devoted to the clinical examination of the urine, and the third section is devoted to the consideration of diabetes mellitus, its complications and treatment, and to diabetes insipidus. The last section treats of renal calculus, hydronephrosis, pyonephrosis, pyelitis, hematuria, and hemoglobinuria. Each section is casuistically treated as well.

The work represents the present knowledge of renal and urinary diseases. It is admirably written and is accurately scientific. The illustrations are well executed and the book is handsomely made.

CLINICAL LESSONS ON NERVOUS DISEASES. By S. WEIR MITCHELL, M.D., LL.D., Edinburgh, Member of the National Academy of Sciences; Honorary Fellow of the Royal Medico-Chirurgical Society of London. Pp. 299, with illustrations and two colored plates. Philadelphia and New York: Lea Brothers & Co., publishers, 1897.

WHATEVER Dr. Mitchell writes is worth reading. He represents the knowledge of the special department of medical science that is associated with his name. Neurology is the richer in facts and principles because he lives and works. This little book is made up of a number of clinical lectures delivered by Dr. Mitchell at various times. It is replete with facts and represents to the medical profession some of the results of the author's vast knowledge and experience.

The clinical cases illustrative of the subject of each lecture are well selected and graphically presented. We should like to see the entire field of neurology covered by the author in the same manner.

TWENTIETH CENTURY PRACTICE. AN ENCYCLOPEDIA OF MODERN MEDICAL SCIENCE BY LEADING AUTHORITIES OF EUROPE AND AMERICA. Edited by THOMAS L. STEDMAN, M.D. In twenty volumes. Volume X. *Diseases of the Nervous System*. New York: William Wood & Co., 1897.

The publishers announce that as the manuscript for Volume IX. is not entirely finished Volume X. has been published in its place.

The first article—on diseases of the brain—comes from the pen of Dr. Joseph Collins. There is a short but complete account of the morphology and anatomy of the brain with a section on cerebral localization. Principally from the clinicopathologic work done, Collins declares that it is fairly certain that the visual center is located in the mesial side of the occipital lobe. After the section on the several varieties of encephalitis the author gives us a good account of the infantile cerebral palsies. The article on hemorrhagic apoplexy is an excellent résumé of the whole subject.

Dr. B. Sachs writes on tumors of the brain, and concludes that, in spite of the few successes in the operative treatment of cerebral tumors, the successful surgical treatment of these within the next decade depends upon improvements in the diagnostic methods of the neurologist and the operative technic of the surgeon. We believe that this is perhaps too rosy a view of the situation, since, according to Hale White and M. Allen Starr, only two to six per cent. of all cerebral tumors justify a surgical operation, and, according to several German investigators, the indications for operation on cerebral tumors are very limited.

Dr. Collins writes on meningitis. In the tuberculous variety, lumbar puncture, as recommended by Quincke, will often ameliorate the severity of the pressure symptoms. This is followed by an exhaustive and scholarly article on hysteria, epilepsy, and the spasmodic neuroses, by Dr. Charles Féré of Paris. Dr. Féré is very emphatic in his assertion that epileptics should be collected in hospitals and never in asylums, and that the education of epi-

leptic children is of great importance and presents great difficulties. We are glad to see that Dr. Féré finds very little justification in the operative treatment of epilepsy, even after all other therapeutic measures have failed. "It must be considered that the cures obtained . . . are doubtful, and it is reasonable to suppose that the improvement observed was not due to the trephining. In fact, it is well known that every violent intervention, whether medical or surgical, may temporarily modify the course of epilepsy."

In the section on neurasthenia, by Dr. Charles L. Dana, we read of a special type of neurasthenia, the "anxiety neurosis," which is surely very closely related to melancholia, if it is not, in fact, an early stage of this mental disorder. Dr. H. T. Pershing, in his article on disorders of speech, gives us a good but somewhat involved account of the physiology of speech and the acquisition of language by the child. Dr. Sanger Brown writes on the disorders of sleep and gives us a good résumé of the subject.

As a whole, volume ten of the "Twentieth Century Practice" keeps up the standard of the previous volumes, and with volume eleven, when that shall have been published, will give us a very complete reference-book for the diseases of the nervous system.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, and Text-Books, of the Leading American and Foreign Authors and Investigators. Collected and arranged, with critical editorial comments, by twenty-seven contributors. Under the editorial charge of GEORGE M. GOULD, M.D. Profusely illustrated. Pp. 1257. Philadelphia: W. B. Saunders, 1897.

It is impossible to critically review a book of this nature, whose object is to faithfully record the advances made in medicine and surgery. When one considers the enormous amount of literature from which the abstracts have been made, it will be seen that it is no easy task to give sufficient space to worthy investigators and to eliminate the results of inexperienced observers. But the editor has shown wisdom in the selection of his collaborators, and the results as shown in this second volume of the "Year-book" are highly satisfactory. As a rule the summary is not a mere outline, but is a careful review of the work, without any superfluous details. In most instances each article is followed by editorial comments, usually critical in nature, which are by no means the least important features of the book.

In a work of this kind it is almost impossible to avoid repetitions, and a few instances have been noted. We believe, however, this to be one of the best of the various year-books with which we are acquainted, and we take pleasure in commending it to every practitioner who wishes to review all the advances made in medicine without the necessity of reading the avalanche of contributions to medical literature.

The book is excellently made up, and is supplied with many well-executed illustrations.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXI.

NEW YORK, SATURDAY, AUGUST 7, 1897.

No. 6.

ORIGINAL ARTICLES.

DISEASES AND TREATMENT OF NASAL ACCESSORY SINUSES, WITH AN ANALYTICAL REPORT.¹

BY ROBERT CUNNINGHAM MYLES, M.D.,
OF NEW YORK;

PROFESSOR OF OTOTOLOGY AND ADJUNCT PROFESSOR OF RHINOLOGY
AND LARYNGOLOGY IN THE NEW YORK POLYCLINIC.

THE etiology of diseases of the nasal accessory sinuses, and their relative frequency, have been receiving considerable attention from thoughtful observers. I have opened six frontal sinuses externally which contained polypoids and pus, and the mucous membrane was found to be undergoing polypoid degeneration. In one case the sinus was opened externally through the anterior wall of the ethmoid cells and the floor of the sinus. This case was due to an extending necrosis from the anterior ethmoidal cells. The membranes were swollen and granular, but there were no polypi.

Two cases of fronto-ethmoidal necrosis were opened through the nose by removing the anterior end of the middle turbinated body, the internal or median wall of the infundibulum and a part of the floor of the frontal sinus. The causes of the necrosis could only be inferred. In polypoid cases I have entered the frontal sinus through the nose many times. The chronic cases which have come under my observation, if considered in an etiologic sense, were about eight to ten in favor of polypoid degeneration.

In ethmoid disease (if we exclude the polypi cases which were not producing suppuration in the cells or bones), about two-thirds of the cases were caused by the polypoid process; the others were due to atrophic rhinitis, and its forerunner, suppurative rhinitis, to non-syphilitic necrosis, supposed to be due to retention of infective secretion, to syphilis, and to new growths. The sphenoidal cases bear about the same ratio. I have three cases of sphenoidal empyema under observation at the present time, all of which have been opened through the anterior upper walls, and they can be probed, curetted, and inspected through these apertures. Two were of polypoid and one of syphilitic origin.

¹ The author's first paper on this subject was read before the Section of Laryngology and Rhinology of the New York Academy of Medicine, January, 1893, and was published in the *New York Polyclinic* for February and March, 1895. A second paper was read before the same Section, January, 1895, and published in *THE MEDICAL NEWS*, March 28, 1896.

From an etiologic standpoint, morbid conditions of the antrum of Highmore are exceedingly interesting. After carefully considering the evidence presented in my series of cases, I have been led to the conclusion that the nose and the teeth are about equal as causal factors of the grave forms of antral disease. In several of my most serious cases of the latter, which were of dental origin, I was principally led to that conclusion by circumstantial evidence, as the teeth had given the patients no trouble for many years, and nothing abnormal was noticed by the dentists who had them in charge. In certain ones I believed that a tooth was the offending cause, chiefly because the odor and character of the dislodged antral secretion indicated necrotic bone, the absence of any information in the general history pointing to any other origin, and the existence of a suspicious tooth, especially when it contained a large filling and had a devitalized color. In some of the cases the fillings were removed and a collection of offensive pus and gas was found at the ends of the roots, which communicated with the antrum; subsequent extraction of the tooth and penetration of the antrum through the alveolus confirmed the diagnosis and cured or relieved the patient.

I will not undertake, in this paper, to explain the causes of polypoid degeneration. I have watched it in all stages and ages, on the ethmoid bone, and on the walls of the respective sinuses. I have seen the flat varieties disappear under favorable conditions, the tissue returning to a normal state without surgical interference. The pedunculated forms have always required some mechanical or chemical remedy. The watery infiltration seems to affect only certain persons who have a peculiar predisposition.

The diagnostic points have been rather fully considered in my previous papers. I desire to emphasize the point that the silver irrigation tube and the small trocar and cannula are invaluable aids in cases of doubtful and difficult diagnosis. The tube should be passed through the natural opening when possible. The trocar and cannula can be passed through the internal wall of the antrum just below and posterior to the hiatus semilunaris, directing the point downward and outward through the wall of the inferior meatus, and through the canine fossa.

The general pathology of each of these cases should be carefully thought out before the operation is undertaken, although not so much depends upon

the pathology as upon the extent of the process. Polypi do not signify much, but the degree of degeneration means a great deal. A small carious or necrotic area at the end of the tooth-root is usually cured easily after the extraction of the tooth. Burrowing periostitis, extending over the floor and a part of the walls, will frequently get well after drainage has been established and irrigation properly carried out. It is in this class of cases that great injury is done by what is termed "thorough curetting." The membrane is separated from the bone by pus cavities after the manner of fistulas. If the membrane is not removed, it will, under proper treatment, frequently regain a rather normal appearance, the apparent granulations and infiltrations disappearing, and will reunite to the supposedly carious bone beneath.

In those cases where the symptoms and history indicate that the bone disease has existed for many years, I have usually found necrosis varying in area and depth. The dead bone must either be curetted away, or we must wait for Nature, under favorable conditions, to throw it off. The necrosis which penetrates the cancellated parts of the superior maxilla and involves the septa between the tooth-roots, is most tedious in progress and difficult to cure. Retained fermenting secretions create a pathologic condition of their own, which is chiefly a state of hyperemia, infiltration, and irritation, with a proneness to excessive and abnormal secretions. These cases may be associated with a definite pathologic lesion, or may be kept up by the leaven from old-time degenerating matter; surgical interference will relieve the former while irrigation will frequently cure the latter.

Since our treatment must be governed by the pathologic state within the cells, and since in some cases it is impossible to determine the exact tissue changes, we must divide the treatment into expectant, exploratory, and positive methods. In all acute and subacute cases it is our duty to use the expectant or the exploratory method. In the chronic cases, where there has been not only decided destruction of the tissues, but new formations in the way of tough granulations, polypi, devitalized and necrotic bone, surgical interference is imperative. There are many cases where the evidence points conclusively to necrotic changes within the hidden area.

The expectant treatment consists of restoring the nasal chambers to their normal condition, either by surgery or by chemicals, the use of soothing and disinfecting sprays or applications, the gentle introduction of tubes and irrigation of the sinuses through the natural openings, together with attention to the general health of the patient.

Exploration in antral disease is carried out by simple penetration and irrigation of the cavities through the canine fossa, the walls of the middle and inferior meati, and by Zeims' method. "When the set of teeth is complete the opening is made on the inner side, either between the first and second molars, or between the first molar and second bicuspids." In disease of the frontal sinus and sphenoidal cells, exploratory procedures, which consist of enlarging the natural openings by forcible dilatation or by moderate curetting, frequently afford relief, and in some cases effect a cure.

When we come to a consideration of the cases of sinus disease which demand radical surgical relief, many problems confront us—problems which the recorded experience of the best authors does not seem to solve. In going over the literature upon the subject I have failed to find a description of the pathology of each individual case, a factor which we must appreciate before we can institute and carry out our treatment in an intelligent and logical manner. One author will report a series of cases cured by a certain method, and yet, when one attempts it in a half-dozen instances, it often fails. There are hundreds of cases of sinusitis in which the sinus contains muco-pus without a solution of continuity of the mucous membrane. Nearly all of these cases are cured by tapping, and many of them will recover without any interference, as the disease is more or less intermittent in its course. On the other hand, cases which have existed for many months, and which are accompanied by a rather constant mucopurulent and purulent discharge, with other evidences pointing to necrotic conditions of varying degrees, demand adequate surgical interference.

I have operated upon patients by nearly every method that has been advocated, and the milder types have done well in every instance. There are other cases of the extreme types in which I have successfully used several of the methods which seemed to me to be the most plausible. For instance, in some of the frontal polypi cases I have succeeded in arresting the discharge and relieving the symptoms by the intranasal method. There are several others in which I tried this method for a long time and failed. The cause of the failure was clearly evident when I finally opened the sinus externally. In some of these cases it was remarkable that death had not ensued in consequence of the necrotic and carious condition of the posterior wall of the sinus. In Case III. of my series I pleaded with the patient to permit me to open his left frontal sinus, but he absolutely refused the external operation, and did very well for about one year. After several months ab-

sence from my office he reported and informed me that the sinus had been giving him some pain with very unpleasant symptoms in that region, and that he would consent to the operation. He stated that he would have to go home and arrange some business matters, and would return prepared to undergo the operation at the end of two weeks. Several days later I received a letter from his wife saying that he had suddenly been taken very ill with head symptoms and loss of intelligence, and had died within a few days. There is every reason to believe that this patient would have been cured had he submitted to the external operation. In his case, although the antrum had been opened through the tooth socket, it had to be reopened on account of the natural closure of the cavity. The polypi continued to recur and trouble him; many of them were never curetted away on account of the inability to use the instrument properly through the opening, the walls of which were equal in depth to the perpendicular diameter of the alveolus. I have adopted the rule of operating externally in those cases of frontal sinus disease in which the symptoms are profound, and fail to yield to intranasal methods of treatment.

Luc of France reports most excellent results from the removal of the floor of the frontal sinus, and immediate closure of the wound after the operation. I have removed part of the floor in some of my cases, and used nasal drainage tubes; large granulations sprang up from the parts which were cut, and gave me more trouble than when the mucous membrane was left on the bone. I presume I did not remove enough of the nasal process of the superior maxilla, which forms the thick part of the floor. I shall try the method of removing nearly all of this part of the floor in a future case; we must remember, however, that the space between the thin, bony wall next to the brain, and the floor of the sinus, may be twice as great in one case as it is in another.

As the infundibulum walls are also the walls of two or three anterior ethmoidal cells, of course, when the canal is enlarged, it is done at the expense of the cell walls, and it is preferable that this should be done with some smooth or soft substance, for destruction of the mucous membrane of the canal produces granulations which ultimately obstruct the passage of the secretions. In severe cases it is well to remove a part of the anterior ethmoidal cells.

In the extreme polypoid cases the ethmoid bone is rather brittle, and parts can easily be removed. The bone is almost flinty hard in the suppurative cases. After the middle turbinated bone has been removed, I drill or gouge an opening through the floors of the anterior and posterior cells, and then pass the anteroposterior clippers into the cells and

cut away as much of the floors as I can. In some cases I use the lateral clippers to remove the thick part of the floors, and a part of the internal lateral walls. I have relieved all cases by this method, and cured some; many of them continue to secrete a certain amount of a glassy, mucopurulent substance, which seems to come from the little cells which are situated in the deeper recesses.

The sphenoidal cells are not so difficult to open as some are inclined to think. In cases in which the septa are moderately straight, and in which the posterior end of the middle tubinated bone has been removed, the oozing pus can easily be detected at the point of the natural opening, high up and near the septum. The probe will often enter after careful use; a small, sharp, firm curette, passed in and then pulled outward will usually tear away the sides of the opening sufficiently for good drainage. I do not consider it safe to curette the upper and external walls of these sinuses. Careful scraping of the anterior wall and the floor often produces decidedly beneficial results. There has been much discussion about the distance from the margin of the nasal vestibule to the sphenoidal cells. If the measurements are taken from the point of exit of the natural canal to the center of the septum in front they will vary from $2\frac{3}{4}$ inches to $3\frac{1}{4}$ inches, and about one-fourth of an inch less if the middle of the ala is selected. Of course, the face must be composed, for contraction of the muscles will increase or diminish these measurements about half an inch.

Some good surgeons have made the statement that diseases of the antrum of Highmore should be treated on general surgical principles, as diseases of other cavities are treated. I beg to differ with them for many reasons. For instance, the mastoid cells can be obliterated and refilled with tissue and depressed integument. Who would be guilty of removing the external wall of the antrum maxillare and allowing the integument to adhere to the internal wall? This would effect a complete cure, but produce a hideous deformity. Who has not regretted the removal with the curette of an apparently hopelessly diseased mucous membrane, and the periosteum of this thin-walled cavity, and watched through many months the slowly recovering process by granulation tissue? Who has not watched a membrane, apparently beyond physiologic repair, do better without radical surgical interference than similar ones which had been over-curetted? The improvement in the treatment of antral disease will be made in the direction of effective, but conservative surgery.

When a stubborn case is presented the surgeon must decide whether he will operate through the nose, by penetrating the antrum wall, either through the

inferior or middle meatus; or through the tooth-socket and alveolus, after Cooper's method; or through the canine fossa, Desault's method; or through the inner side of the alveolus, near the junction of the hard palate and alveolus, as recommended by Zeim; or through the malar ridge, which I believe was first strongly advocated, in certain cases, by the writer. Probably there are cases in which each of these operations, respectively, would be the best. The judgment of the operator, which must be based upon experience and a careful consideration of every point, must be relied upon for the proper selection. In those cases in which the evidence points to a tooth as a cause, I would advise removal of the tooth and penetration of the antrum through the socket which contained the diseased root. This is such a simple and harmless procedure that it is well to employ it as an expectant treatment, excepting in the very grave forms of disease. I prefer the operation through the malar ridge and canine fossa in all instances when the symptoms indicate that the tissues are extensively degenerated.

CASE XLVI.—Mrs. D., aged twenty-eight, consulted me during March, 1895. She gave the following history: During March, 1894, she began to suffer from a copious discharge from the posterior nares, and two months later a dull, aching pain began in the right upper jaw, which increased, and extended to the eye. An ulcerated tooth was removed from that side, and the dentist made a diagnosis of empyema of the right antrum. He drilled into the antrum, and found pus which was very offensive. He treated it daily for about two months, with but little relief. The electric light produced a dark umbra under the right eye, and there was a bright spot beneath the left eye. Muco-pus flowed from the hiatus downward and backward over the posterior tip of the inferior turbinated bone. I curetted the antrum as well as I could through the small opening on different occasions, and treated the patient a few months, with but little relief. There seemed to be extensive necrosis and caries of the floor and the anterior and internal walls of the antrum. At the New Amsterdam Eye and Ear Hospital, the patient being under ether, I made a large opening into the antrum, removing the external part of the alveolar process, and extended the opening up into the canine fossa. The walls were rough, carious, necrotic, and covered in places with ugly suppurative granulations. This surface was carefully and deeply curetted, the cavity packed with gauze, and there was decided improvement in the symptoms. The aperture was kept open with a large rubber tube for several months, and recuretted at intervals of about six weeks. Exuberant granulations would spring up, and also circumscribed areas of carious and necrotic bone, preventing cicatrization. The membrane gradually closed around the tube, which I excised under cocain with a Graefe knife, and the diseased area gradually lessened and

improved. At present there is a slight amount of mucus, but this is not troublesome, and the symptoms of diseased bone have disappeared. There are still many rather firm granulations which seem to be cicatrizing over the region which was deprived of its mucous membrane and periosteum.

CASE XLVII.—Mrs. H., aged twenty-seven, applied to me for treatment during 1895. She gave a history of nasal discharge, which dated back to her infancy. About three years before I saw her pain commenced in the face and head, which was more severe on the left side. There was a discharge of matter and crusts from the nose, and her headaches had been so severe that morphin was necessary to relieve her. She had also suffered from photophobia. The electric light produced an umbra beneath both eyes. Mucopurulent crusts were lying in the middle meatus, near the antrum of Highmore opening, and there was a general appearance of atrophic rhinitis. During April, 1895, I drilled through the malar ridge (the first molar tooth being absent), making an opening about eight millimeters in diameter, and found that the cavity contained pus, muco-pus, and some granulations. I curetted it very carefully, and inserted a rubber tube, and irrigated the cavity regularly. The incrustations in that region, which indicated atrophic rhinitis, disappeared entirely, the pain ceased, and the patient improved remarkably.

CASE XLVIII.—Dr. S., age forty, applied to me during the spring of 1895. He was suffering from an unpleasant nasal discharge, which was confined to the right side, headaches, and a constant dripping into the throat. He had suffered from this condition for about one year. Examination demonstrated muco-pus in the middle meatus and around the middle tubinated body. There was a slight deflection of the septum, with rather a large exostosis pressing into the under surface of the inferior turbinated and the parts around the hiatus. I made the diagnosis of ethmoiditis and exostosis. The parts were so pressed together in the middle meatus that it was impossible to arrive at any definite conclusion as to the extent of the disease. I sawed off the exostosis and removed a part of the tubinated. After treating him for several weeks the secretion lessened. At his own suggestion my attention was directed to the antrum, in which region he complained of a peculiar sensation. I passed a tube into the antrum, and on irrigating a quantity of very offensive pus came away with the fluid. These irrigations were kept up for some time, and he improved to a certain degree. He continued, however, to be annoyed by a discharge of muco-pus, but in a much lesser degree than before. I had noticed a defective first molar tooth, and suspected that it was the cause of the trouble. I requested him to have it extracted, which he did, and necrosis was found at the end of the root. The antrum was irrigated through the socket for several weeks, and he improved steadily, and in six months was apparently well.

CASE XLIX.—Miss S., aged twenty-two, applied to me in June, 1895. She gave a history of having had polypi removed from the nose since her fifteenth

year. Upon examination, polypi and pus were observed in the right middle meatus. The electric light showed a dark umbra beneath the right eye, and produced a light spot beneath the left eye. The polypi were removed with the snare and forceps, and pus continued to ooze from the antrum. During the previous March she had had an abscess at the root of the first bicuspid tooth, accompanied by intense pain and neuralgia extending over the entire right side of the face and behind the ear. This yielded only to heavy doses of opiates, and at the end of two weeks it suddenly disappeared. On June 14th, under ether, I performed the canine fossa operation, making an opening large enough to admit my little finger. The cavity was full of pus, granulations, and polypi. The cavity was curetted and packed with iodoform gauze, and redressed on the 16th, 17th, and 19th. After this she had some nausea and pain, with a temperature of 100.6° F., and also attacks of depression, "smothering," and wheezing. All the packing was removing and the cavity was insufflated with aristol. The patient improved rapidly. A soft rubber tube was kept in place for several months, and the discharge gradually ceased. The opening was allowed to close. I examined her on February 4, 1896, and found both antrums bright by transillumination; there was a very slight collection of muco-pus in the right middle meatus, apparently coming from the ethmoid. The patient feels that she is entirely well.

CASE L.—Mrs. C., aged fifty, applied to me on July 11, 1895. Her previous history was that pain had commenced fifteen years before in the left upper jaw, and had continued for ten years; then an abscess discharged into the left nostril from the antrum. The last molar tooth was extracted and found to have an exostosis on the fang. Her physician advised that the antrum be entered through the socket. This was done, and considerable pus came away. It continued to flow for two years, and the cavity was reopened twenty-two times. She never had been free from postnasal catarrh. Five years ago the right antrum began to be painful, and this continued until one year ago, when she consulted Dr. Roe of Rochester. He drilled into the right antrum, through the side of the alveolus, and removed pus, fungous growths, and polypi. She wore a tube five or six weeks, the wound closed, and she gained twenty pounds during the year. She had been suffering from a pain in the right antrum for the past few months, felt nervous, could not sleep, had chills, and muco-pus flowed into the throat constantly. On examination I found the middle turbinate hypertrophied, and a certain amount of suppurative ethmoiditis; pus was oozing from the left meatus, and the left infundibulum. The electric light produced a dark umbra beneath the left eye, the right being normal. She complained somewhat of the right antrum, and several surgeons had insisted upon reopening the cavity under ether. I tried to convince her that the right antrum was well, but in order to do this I made a small opening through the flesh which had grown over the aperture made by

Dr. Roe, and irrigated the cavity. The fluid came through clear, without a trace of pus. On November 8, 1895, I opened the left antrum through the malar ridge. The cavity was full of pus and granulation tissue. I curetted it carefully, packed it with iodoform gauze for a few days, and then inserted a rubber tube. The patient improved rapidly. I received a letter from her on February 20, 1896, in which she stated that she thought the antrum was entirely well, but that she was still wearing the tube. She expressed herself as being entirely relieved from the severe suffering which she had endured for nearly seventeen years.

SURGICAL TREATMENT OF EMPYEMA.

BY H. A. LEIPZIGER, M.D.,
OF BURLINGTON, IOWA.

ABOUT twelve or thirteen hundred years ago, Paulus Ægineta, the recognized authority in medicine and surgery, had this to say about the surgical treatment of empyema: "The most effectual remedy which has been discovered for empyema is burning, wherefore the parts are to be burnt by applying the root of the long birth-wort soaked in oil, so as to form eschars, one of which we must make between the juncture of the clavicles, and two small ones a little distance from the chin and remote from the carotids, two of considerable size below the mammæ between the third and fourth ribs, two others between the fifth and sixth backwards, another at the middle of the sternum, and another above the mouth of the stomach, three behind, one at the middle of the back, and two on each side of the spine." Leonidas said: "Others, having passed a knobbed cautery through the interstice between the ribs to the abscess, have carried the burning down to the pus. Some have dared to operate upon them by making a transverse incision or one a little obliquely in the skin between the fifth and sixth ribs, then perforating with a knife the membrane lining the ribs and thus evacuating the pus, but they, and those who burn with iron to a considerable depth, either occasion immediate death, the vital spirit being evacuated with the pus, or occasion incurable fistulæ."

Several hundred years before this writer, Hippocrates referred to and recommended paracentesis for the treatment of empyema. At the present time, if one visits any large metropolitan hospital and inquires if any special operations are to be performed, one is likely to hear in an indifferent tone from the busy house surgeon that there may be also one or two "Estlanders," as though the Estlander operation was either a very minor affair or, at least, a daily occurrence. And so it really is; and when I say that it appears to-day to be the recognized treatment for empyema, at least of the chronic form, I have

about covered the ground selected for this paper, and it only remains to describe the operation and to mention, as a matter of historic interest, the various other forms of treatment and their originators.

The Estlander operation was reported in a Scandinavian medical journal in 1879, and consists essentially in the removal of portions of as many ribs as will tend to approximate the chest walls and the lung pleura at the site of the pus cavity, and thereby obliterate the cavity or encourage gradual filling out of the lungs. The operation is recommended when the disease is of long standing and the pleura very much thickened. The point chosen for the operation is that portion of the thorax beneath the axilla, as this locality is destitute of large muscles. If a fistula exists, it serves as a counter-opening; if none exists, a counter-opening must be made. Ordinarily the author of the operation made transverse incisions between the ribs; by a single incision he has laid bare two ribs and sometimes three. The resection is subperiosteal and, of course, is executed under strict antiseptic precautions. The fragments removed are from three to six centimeters in length.

In looking up the subject, I came across the following report of a case of American thoracic surgery occurring in 1858, which was very much like the Estlander operation, although the former was not done for empyema: A Dr. Cooper reports in 1858 to the San Francisco Medico-Chirurgical Society the case of a young man wounded by a slug of iron, which entered his left side, fracturing the sixth rib and remaining in the chest seventy-four days. The patient at this time was greatly prostrated, pus was being discharged from the opening made by the slug, the left lung had lost its function, and dyspnea was now alarming. A T-shaped incision was made, the soft parts reflected to expose the ribs, and an effort made to find the slug with a probe. Not succeeding, portions of the fifth, sixth, and seventh ribs were removed. In doing this, a discharge occurred of about ten ounces of bloody fluid, followed, upon breaking up some attachments, by another discharge of at least two quarts of pus. The pleura was very much thickened. The patient seemed to be rapidly sinking, and was given brandy freely and, after a time, chloroform. The thoracic cavity was explored for at least three-quarters of an hour with a sound, and the foreign body finally found by passing the instrument between the heart and the descending aorta. The forceps, following the sound as a guide, could not be opened without lifting the apex of the heart considerably out of its natural position. The patient recovered rapidly, and at the expiration of a few months seemed as well as before the operation, although the left breast remained somewhat sunken.

Dr. Daniel Brainerd, in 1857, reported a case of empyema treated by injection of iodine. He used a gum-elastic tube of the size of a No. 9 catheter and washed out the pleural cavity night and morning during several months. The patient recovered. In 1860, Dr. Goodfellow dilated upon the successful result of drainage in empyema. He inserted a rubber tube through the fistulous opening or puncture made by a trocar and pushed the tube through a counter-opening made posteriorly and low down. In 1873, Dr. J. Sheperd Fletcher reported a case of empyema cured by five operations of paracentesis and the use of a drainage tube. In 1877, Dr. J. G. Blake of Boston advocated free and early incision in the treatment of pyothorax as soon as the presence of pus was determined, and the subsequent washing of the cavity with antiseptic solutions as soon as the discharge became offensive. In 1879 the Estlander operation was first described. In 1881, Professor King reported decidedly in favor of free incision and drainage whenever pus was present, claiming recovery in from one to three weeks when a strong solution of chlorid of zinc was used. In 1882, Professor Dieulafoy emphasized the fact that it is impossible to transform a simple into a purulent pleurisy by thoracentesis with clean instruments.

Baccelli, an Italian physician, maintains that the nature of the liquid within the chest can be ascertained by means of the whispered voice. If the liquid is serous the whispered voice is well transmitted through the liquid and is pectoriloquous, but is not well conducted when purulent. Dr. Austin Flint did not place much dependence upon this means of diagnosis, asserting that the nature of the liquid can be ascertained much more rapidly and equally as safely by exploratory puncture. In 1882, Dr. Bruglocher advocated the practice of resection of several ribs in cases of long-standing empyema in adults. In 1884, Dr. Janeway called attention to the danger of general anesthesia in operations for empyema, particularly when there is perforation of the lung. He allows the fluid to run out until the patient feels distressed. Dr. Beverly Robinson advises tapping several times before resorting to radical operation. Dr. A. A. Smith thinks the hypodermic exploration alone sometimes favors absorption.

Dr. J. Fayee Finney reports a case of sudden death in fibrosis of the lung from a somewhat rapidly accumulating pleural effusion, emphasizing the necessity for the removal of these accumulations in cases of phthisis.

In the *Lancet* for January, 1886, Mr. R. J. Godlu says that children recover from the various operations and dispose of the residue of pus more easily than adults. In several cases a single aspiration in

each effected a permanent cure. If aspiration has been employed several times without success, he advocates fully opening the cavity a little below and outside the lower angle of the scapula and excising parts of the eighth and ninth ribs. In doing Estlander's operation he prefers removing the thickened periosteum. In children, an attempt to dispense with drainage may be made much sooner than in adults, in whom the tube should be worn as long as pus is discharged. Patients with phthisis and empyema should not be operated upon unless the latter is causing much inconvenience. The same applies to cases in which the pus is quietly discharged through the bronchi.

Cormack reported forty cases in which there were ten fatal results from Estlander's operation and ten complete cures. The procedure is best carried out after an interval of from six to twelve months has elapsed since the formation of a fistula. A very large cavity, extensive tuberculosis, and communication with a bronchus are contraindications. In 1886, Dr. Kassanali reported twenty-one cases treated by slow, gradual drainage, free drainage with a tube being used only when the chest cavity had been entirely emptied. The tube was removed on the thirty-fourth day, recovery being expected on the forty-fourth day. A rib was not removed. In 1887, Dr. W. H. Strickler described a modification of the Estlander operation. He removed enough of the fifth, sixth, and seventh ribs to allow of exploration of the whole pleural cavity with the entire hand, except the thumb, removed bands likely to hinder expansion of the lung, and removed all fibrinous masses. Five successful cases were reported. In 1889, Dr. William Williams described a treatment by means of a valvular tube, the principle of which consisted in removing atmospheric pressure from the external surface of the lung while the opening in the chest wall still remained, thus enabling the lung to fulfil its function and fill up the side of the chest from the first without waiting for any falling in of the side. He reported three favorable results. In 1890, Dr. Pel presented an excellent analysis of one hundred cases, and in summarizing, said that the radical incision, sometimes combined with resection of the ribs, is by far the most efficient method, and is the only one which assures definite results. In very recent cases, however, the radical operation must not be too quickly undertaken, not only on account of danger of infecting the pleura from without, but on account of a recrudescence of the pleural inflammation. An expectant procedure is adapted to those cases in which there is a small circumscribed empyema, without such symptoms as fever, general weakness, rapid pulse, and disturbed digestion. In 1890, Dr. Voël-

ker reported a death from neglected empyema in which perforation of the esophagus and erosions of ribs took place.

In July, 1891, Dr. Henry Koplik published an article on the "Etiology of Empyema in Children," in which he credited the first aspiration and exploratory puncture of the pleural cavity to Bowditch, the American physiologist. His cases were all treated by resection and drainage, and when, as in two cases, the pus became putrid, he attributed this not to admission of air into the pleural cavity nor to bacterial infection from the lips of the wound, but to retention due to insufficient drainage or want of proper expansion of the lung. Dr. Handford of Nottingham, England, reported a double empyema following an illness of three-weeks' duration in a boy seven and one-half years of age, in which both sides were resected at intervals of ten days by removing a piece three-quarters of an inch in length from one rib on each side. Both tubes were removed at the end of nine weeks. Dr. E. M. Light of Leeds, England, reported three cases of pulsating empyema cured by aspiration and drainage.

In March, 1891, a committee of the Belgian Academy of Medicine reported upon the status of the Estlander operation. The report set forth that while this operation occupies a legitimate place in surgical practice, its use is not absolutely necessary in all cases of protracted and extensive empyema. Verebelaje, January, 1891, held resection of a rib generally to be unnecessary, and only indicated when approximation of the ribs hinders free exit of pus. He is in favor of frequent washings with lukewarm 30-per-cent. boric-acid solution, and reports recoveries in from 70 to 80 per cent. of his cases.

Popon states that the literature of this subject shows that prior to 1877 only thirty-six cures after puncture of the pleura had been reported, and of this number there were only seventeen recorded cases of permanent cure. From 1877 to 1883 there is a record of twelve additional cures. During the same period there is a record of 151 radical operations, with 120 cures. From 1883 to 1892, 70 cases were reported, with 9 deaths. During the same period only two successful punctures were reported, hence the radical operation in children is to be preferred.

Dr. Edward Martin reports eight cases, and advises simple puncture in recent cases as the first operative intervention. If this is not sufficient, incision in the fifth intercostal space should be performed. Despite the opinion of Schede and Ziemssen, resection should be reserved, in the author's opinion, for exceptional cases. In August, 1892, Drs. E. B. Hastings and Harford N. Edwards presented a report of the then condition of twenty-four children upon whom the

operation of resection of the ribs for cure of empyema had been performed from one to seven years previously. Careful examination revealed a completeness of recovery in the majority of cases which was surprising. Dr. Rust reports thirty-three cases treated by aspiration and drainage. In eleven clear cases without complications, ten patients recovered, the average duration of treatment being 274 days. The result in all cases, regardless of etiology and complication, is much less favorable, the figures being: cured, 52 per cent.; improved, 18 per cent.; died, 30 per cent.

In June, 1894, G. A. Sutherland reported four cases of double empyema treated by double resection, irrigation, and drainage. He attributed the rapid recovery to his having employed temporary drainage—that is, only seven days, instead, as formerly, seven weeks. The most expanded side should be operated on before the other, as simultaneous drainage has caused alarming collapse. An important part of the after-treatment is forced respiratory movements and chest-expanding exercises. In 1895, Edmund Cantley of London published his deductions founded upon the records of eighty-six cases of patients under twelve years of age. He does not believe the chances of perfect cure are better under treatment by resection, as more of the patients were discharged with a sinus than in the cases treated by incision. Early contraction of the side follows resection more frequently than incision. He states the indications for resection as follows: (1) When the closeness of the ribs prevents drainage; (2) when drainage after the simpler operation is imperfect, as shown by high temperature and offensive discharge; (3) when the lung has re-expanded and the chest walls have contracted, and yet the sinus does not close. In double empyema he thinks the best treatment is simple incision and drainage at intervals of a few days between the two operations. He first aspirates both sides, relieving the heart from pressure, next day operates on one side, preferably the left, and a few days latter on the other. Local anesthesia should be used when the effusion is general on one side and localized on the other, the full side should be operated on first. In double localized effusion, simultaneous drainage may be adopted, but it is wise to wait a few days between the two operations. Dr. G. C. Cumston reports six cases of cure by means of the siphon of Revilloid. This siphon consists of a tube of black rubber three feet long, inserted into the pleural cavity. Two feet from the proximal end is placed a bulb, and the distal end is placed in an antiseptic solution. The proximal end is held in place by plaster. There is no resection of the ribs.

OBSTRUCTION OF THE BOWELS.¹

By A. C. TAYLOR, M.D.,
OF DULUTH, MINN.

On the afternoon of December 25, 1896, I was called to the village of Two Harbors to see a young man, who presented the following history: He was sixteen years of age, strong and well-developed, and never had had any illnesses other than those incidental to childhood. On December 20th he had slight colicky pains, which induced him to take a laxative, which gave him relief. No amount of questioning elicited a history of pain previous or subsequent to that time until the following Thursday (the 24th), when he had more or less pain all day, but not of a character so severe as to cause him to make any complaint until evening, when it became so marked that the family physician, Dr. J. D. Budd, was sent for. Dr. Budd at once attempted by the use of saline cathartics and enemata to move the bowels, but without success. Vomiting commenced about 10 P.M. and continued until 4 A.M., when it subsided until about four in the afternoon. Cathartics were not administered after vomiting commenced, but injections of water, glycerin, olive oil, etc., were freely tried, until the rectum became so irritable that this method of treatment had to be abandoned. During all of this time the patient had not received opiates, so that when I arrived, at about 4.45 P.M., on Friday, the 25th, the symptoms were in no way obscured. I found him with a pulse of 100, temperature 103° F., respirations 20, pain remitting, countenance fairly good, and constipation complete. At about 4 P.M. he had vomited nearly a quart of yellowish material, evidently from the intestines, but free from stercoraceous odor. He had not taken anything solid or liquid into the stomach since early morning. He had frequent eructations somewhat resembling singultus. Tympanites was slight, but pain and tenderness were extreme, being greatest in the left iliac and lower central part of abdomen, with a limited area of dullness midway between the umbilicus and pubes. Peristalsis, as determined by auscultation, ceased at this point.

I diagnosed an acute obstruction, with a local point of inflammation, due to an unknown cause, and decided that an operation offered the only hope of saving the patient's life. The attending physician concurring in this view, as soon as preparations could be made, which required a few hours' time, the abdomen was opened in the median line, and the exploring finger soon came in contact with a mass of recent adhesions involving the ileum. The abdominal incision was then enlarged and the whole mass carefully lifted out on warm towels. The adhesions between the coils of intestine were broken up, when the cause of the trouble was found apparently to be a volvulus, but which upon further investigation proved to be a diverticulum. This loop or sac had become strangulated, probably from stasis of fecal matter, and gangrene and perforation had occurred, the opening being as large as the end of the little

¹ Read before the St. Louis County Medical Society, March 1, 1897.

finger. The loop was removed, with sufficient of the gut to allow of healthy tissue being obtained on each side, probably six or eight inches in all, and the ends of the divided gut were brought together and united with the Murphy button.

On the following day the boy's temperature was nearly normal and his pulse about 86. His recovery was uneventful, except that following the separation of the button, which probably occurred on the seventh or eighth day, there was considerable gripping pain, with constipation for two or three days, while the button was passing through the last few inches of the ileum. The button was passed on the eighteenth day.

Determination of the method of treatment in a case of ileus must depend upon an accurate diagnosis; and this is the point which I desire to bring out in this discussion. In making a diagnosis we must depend, *first*, upon the history; *second*, upon the symptoms, and, *third*, upon physical exploration. In order to fully understand the lessons which these teach, and to draw proper inferences from them, the causes which may produce obstruction must be understood.

For convenience, I shall consider the causes of ileus under nervous and mechanic heads. The nervous causes I divide into (*a*) direct, (*b*) reflex, or, if it is preferred, central and peripheral. Among the direct or central nervous causes we find spinal paralysis from injury or disease of the spinal cord, injury or disease of the splanchnic nerves, and narcotic and ptomain poisons, such as opium and tyrotoxin, and, I believe also, the salts of lead. To the reflex or peripheral causes may be ascribed the passage of renal or biliary calculi, a compressed ovary, peritonitis from all causes, and perhaps also simple mucous ulcer. Among the mechanic causes we have simple obstruction from foreign bodies, such as impacted feces, enteroliths, biliary calculi, etc., and constriction of the lumen of the gut or of the blood-vessels supplying the part, or both.

Of all the various symptoms which may and do arise in these cases, there are but three which are common to all, *viz.*: persistent pain, persistent constipation, and persistent vomiting. (In intussusception in children it is to be remembered that mucous and bloody diarrhea is frequently present instead of constipation.)

Let us now observe some of the points characteristic of each of the above divisions, if any can be found, by which we may determine to which class a case belongs. Ileus, from central or direct nervous causes, will present a history of injury or disease of the nerves, retention of urine, and altered reflexes. In opium poisoning there is slow respiration, contraction of the pupils, and somnolence. In lead poisoning

the occupation of the patient, the blue line on the gums, and retraction of the abdomen, will serve as a guide to a correct diagnosis. Ptomain poisoning is not so easy to distinguish, but usually there will be convulsions or muscular tremor, paralysis, and dilation of the pupils.

Taking up the reflex or peripheral division, we find that in biliary calculi assistance in arriving at a correct diagnosis is rendered by the history of previous attacks, by the character and seat of the pain, and by the presence of jaundice and a slow pulse. In renal calculi there will probably be a history of previous attacks, which, together with the character and location of the pain, which is peculiar and which probably precedes the symptoms of intestinal obstruction, makes the diagnosis tolerably certain. In compression of an ovary, a vaginal examination will reveal a displaced organ which is tender to touch, or which is pressed upon by a tumor or adhesion. The temperature and pulse are not much altered unless the condition is accompanied by local peritonitis.

In ileus due to mechanic causes, fecal impaction is easy to diagnosticate, through the presence of the soft, nodular, doughy mass, which nearly always is located in some portion of the colon or rectum. The slow development and flat percussion note of the mass are also important factors. The presence of other foreign bodies, such as impacted biliary calculi, and enteroliths, is not so easily recognized, and my belief is that a diagnosis is impossible except by ocular or direct digital examination.

We may, then, in a case of ileus, easily recognize any of the above conditions when they are present, or eliminate them if not present, with the exception of the two last-named. We will then have left the cases due to constriction either of the lumen of the gut or of the blood-vessels, or both. These cases may be divided into the chronic and acute variety. In the chronic cases may be found tumors and abnormal growths involving the intestinal tract or mesenteric vessels, contraction of cicatrices, adhesive bands, etc. In the acute class will be found wounds of the gut or vessels, intussusception, strangulation, as in hernia, volvulus, or slipping of a portion of the intestine through loops of adventitious growth.

Intussusception may be inferred by the age of the patient, acuteness of the attack, severity of pain with periods of intermission, and occurrence of mucous and bloody stools. In one-half of the cases a tumor can be felt in the left inguinal region. External strangulation, as in hernia, is, of course, easily diagnosed. Internal strangulation, by volvulus or otherwise, usually can be made out by the acuteness of the attack, severity of the pain, and occurrence of shock and tampanites, peristalsis ceasing at the point

of strangulation. Whether there be tumefaction at the point of constriction depends largely upon the manner in which the compression is made. Experiment upon animals has shown that constriction of the mesenteric vessels, if the parallel artery is intact, causes an edematous condition of the intestinal walls, with transudation of fluid into its lumen; whereas, if the parallel artery also is constricted, death of that portion of the gut is immediate, and no distention, but rather absorption, takes place. (Murphy.)

From a surgical standpoint, cases of ileus resolve themselves into two classes—operative and non-operative. The question always before us, then, is, will the patient recover without surgical interference? Unfortunately, we cannot always decide this point. Cases which I have classified as of nervous origin, whether due to central or peripheral causes, including peritonitis, must be classed as inoperable.¹ In the second division, or mechanical cases, with the exception of instances of fecal impaction, the indications change, and surgical interference is almost the only course offering hope of success and should not be delayed a moment after the diagnosis has been established.

Of the treatment by distension with water, or inflation with gas, I can only speak in order to condemn. Take the case I have just cited, in which the perforation was sealed to the omentum and adjacent coils by plastic lymph only thirty-six hours old, as an illustration. Even a moderate amount of distension, by straightening out the coils, would have broken up these adhesions, opened the perforated gut, and caused an outpouring of fecal matter into the free peritoneal cavity, and death of the patient would have been inevitable, or, at least, highly probable. It appears to me that those who recommend distension with fluid equal to a pressure of four atmospheres can have had but little experience with the treatment. Dr. E. Martin of Philadelphia, while recommending this procedure, admits that it should not be made use of when the obstruction has existed for more than three days, owing to the possibility of gangrene or perforation having occurred, and advises that the surgeon be prepared to operate immediately in case rupture occurs. In the case cited above, perforation had certainly occurred within forty hours, and probably within a much shorter time.

One word regarding the so-called exploratory incision as a means of diagnosis. While in all cases in which an operation is performed the first incision should be small, only large enough to allow the oper-

ator to decide upon the nature of the disease, and the steps which are necessary to complete the operation, I believe that a small exploratory opening does not accomplish much in the way of diagnosis in intestinal obstruction, nor do I believe that it should be lightly undertaken. For instance, suppose an exploratory incision is made in a case of obstruction from any of the nervous causes mentioned in my classification. Teachers tell us if we find nothing, to sew up the wound and no harm will have been done; but in practice one finds a uniformly distended gut, and I have seen the whole ileum pulled out of the wound before it was decided that there was no cause for operation.

CLINICAL MEMORANDUM.

TUMOR (GLIOMA) OF THE LEFT TEMPORAL LOBE OF THE BRAIN; ATTEMPTED REMOVAL.

BY M. ALLEN STARR, M.D.,

OF NEW YORK;

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM
IN THE COLLEGE OF PHYSICIANS AND SURGEONS; CONSULT-
ING PHYSICIAN TO THE PRESBYTERIAN, ORTHOPEDIC, ST.
VINCENT'S, AND ST. MARY'S HOSPITALS;

AND

ROBERT F. WEIR, M.D.,

OF NEW YORK;

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND
SURGEONS; ATTENDING SURGEON TO ST. LUKE'S, ROOSEVELT,
FRENCH, AND NEW YORK CANCER HOSPITALS.

THE diagnosis of brain tumor is very easily made, but the exact localization of the tumor is not always so readily determined. Yet this local diagnosis is of the greatest importance, as upon it depends the decision of the possibility of surgical treatment. It is a fortunate fact that the parts of the brain in which tumors can be most definitely located are the parts which are most easily accessible to the surgeon. But the signs and symptoms which make a local diagnosis possible are occasionally misleading. This fact should be regarded in every case, and hence it is well that failures and mistakes should be recorded as well as successes, for one may learn as much from the former as from the latter.

In a study of a collection of 300 tumors of the brain among children, made by one of the writers during 1889,¹ it was found that fifty-six of these were accessible to the surgeon. Sixteen could have been accurately located, and successfully removed. Among the remainder, there were several in which the symptoms pointed to an accessible location on the cortex, but the autopsy proved the site of the tumor to be at a considerable distance from the supposed position, either deep beneath the cortex, or at some distance from it, the symptoms having been produced by pressure transmitted from one part to another. This was also true of the case here reported. The symptoms in this case which indicated the location of the tumor were a slowly progressing motor aphasia, to which was added,

¹ I do not wish to be understood as saying that peritonitis or injuries or disease of the nervous system should never be treated surgically, but that one should not operate upon the intestinal tract to relieve a condition which is purely symptomatic.

¹ "Tumors of the Brain in Children," by M. Allen Starr, MEDICAL NEWS, January 12, 1889.

after three months, a rather rapidly increasing right hemiplegia. The localization was, therefore, made of a tumor in the left third frontal convolution growing backward and inward so as to compress the motor tract in its passage toward the internal capsule. On this diagnosis an operation was undertaken, but it failed to reveal any tumor in the part exposed. At the autopsy, ten days after the operation, the tumor, an infiltrating vascular glioma, was found deep within the apex of the temporal lobe. It must, from its location, have produced pressure inward and upward, as any pressure downward or outward was prevented by the walls of the skull. Such pressure naturally affected the function of the parts compressed, and as there were the third frontal convolution and the Island of Reil with the motor tracts beneath it in the capsule, the symptoms were necessarily misleading. They were indirect rather than direct local symptoms—to use the very apt terms first selected by Nothnagel.¹

It seems in many cases impossible to distinguish clinically between these varieties of local symptoms. Hence, even now, with an experience of 220 cases of brain tumors in which operations have been undertaken, reported in medical journals since 1885, it must be affirmed that in every case an operation for the removal of a brain tumor is an exploratory operation.

The case in question was as follows:

F., aged fifty-five, had been quite well until August, 1896, when she suffered severely from the intense heat, and this, combined with a prolonged mental distress consequent upon the illness and death of her husband, produced a condition of general nervousness. From this she appeared to recover gradually during the month of September, but in October she began to suffer from considerable pain in the head located quite distinctly in the frontal and temporal regions of the left side. This headache was of a continuous, dull, throbbing character, and remained during her illness. It was increased by any physical or mental exertion, by any sudden change of position, especially in stooping, and by the use of nitroglycerin, which was tried as a remedy. During August and September it was noticed by those about her that she would occasionally misuse a name or word, putting it in the place of the word she intended to say, especially if of like sound, but upon being corrected, or upon being asked if she meant to say the word which she had used, she would immediately correct the mistake. This was not very noticeable at the time, but was remembered in view of the subsequent history.

During October and November this defect of speech increased steadily. She noticed a progressive loss of power in remembering the names of old acquaintances and of friends whom she was meeting, and her misuse of words became more and more apparent to those with whom she conversed. In spite of this defect, she appeared to be quite active; she went out and saw many friends, and was vigorous, walking considerable distances, had a good appetite, good sleep, digestion was normal, kidneys were normal, and her headache though constant was never very intense. During the first two weeks of November her

headache become more severe and a marked nervous and mental excitability was evident, with considerable depression of spirits and some embarrassment and anxiety at her supposed failure in mental vigor. She became painfully conscious of her defect in speech and of her loss of memory of words, and the aphasia now increased to the point where all long sentences were avoided and the misuse of words was more constant. At the same time she was conscious of her defects, attempted to correct her mistakes and usually succeeded in doing so. It was now noticed that similar mistakes were made in her writing, that she omitted words, or occasionally repeated words or wrote words which had no relation to the sense. In addition to this progressive aphasia and agraphia there developed during the last two weeks of November considerable physical weakness. She became easily tired upon walking, or upon any exertion, but this weakness did not appear to be limited to one side of the body.

On December 2d, she had a sudden attack, without loss of consciousness, in which she lost the power of speech entirely, and seemed to be very weak, though her radial pulse remained at about 80, her pupils normal and equal and her intelligence active, but there was a marked weakness of the right hand and leg, and she appeared to be very much prostrated. She remained in bed for two days at this time, and when she got up it was noticed that there was slight paralysis on the right side of the body, so that she staggered in walking, dragged her right foot, tended to fall toward the right side and was awkward in the use of her right hand. Five days after this attack, however, she was able to make the journey from Ohio to New York, though she remained in bed all the way, and it was noticed that on her arrival she was weaker on the right side of the body than when she started.

Examination on December 9, 1896, at St. Vincent's Hospital: A large, fleshy, well-nourished woman, apparently in a state of good intelligence, active mentally, observant, and understanding perfectly everything that was said to her. The pupils were equal, and there was no ocular paralysis or apparent disturbance of vision; power of smell normal; optic neuritis was found on both sides, more marked upon the left. Slight, but well-marked, right hemiplegia involving the face, tongue, arm, and leg, without any sensory disturbances, was present. The right side of the face was slightly flatter than the left, and the tongue deviated slightly to the right. The chief loss of power was in the right arm, which was somewhat awkward, had only two-thirds of the power of the left, and was slightly ataxic in its movements. The right leg was dragged somewhat in walking, and was distinctly weaker than the left, so that she staggered toward the right side and was uncertain in her gait. The knee-jerk was increased on the right side; ankle clonus present. Control of the bladder and rectum was perfect.

The condition of aphasia was very marked. She appeared to understand what was said to her, but attempts at talking were confined to single words, and a long connecting sentence was impossible. Her words were occasionally unintelligible and she realized the mistakes that she made. It was as impossible for her to read as it was

¹ "Topische Diagnostik der Hornkrankheiten," Berlin, 1879.

for her to talk, and she could not repeat words after another. Her power of comprehension of things seen was good. She was unable to write, not so much on account of the loss of power in the arm, which was not sufficient to interfere with writing, but apparently because of a true agraphia. She did not seem to be able to recollect how to make the letter, or how to write figures, though when they were written for her she could read them and add them correctly. There was no apraxia. There was no anesthesia of the body and no hemianopsia. Constant pain was felt over the left temporal region, which was sufficient to keep her awake at night, and was the chief cause of her distress. It was quieted somewhat by the use of phenacetin but was markedly increased by the use of nitroglycerin. There was some tenderness on percussion over the left temporal and frontal regions, and a marked difference in the sound of the percussion note upon the two sides of the forehead, it being flat on the side of the tumor.

Diagnosis.—In view of the gradual progressive onset of the disease, headache, optic neuritis, tenderness along the head upon the left side and steadily advancing motor aphasia, followed by right hemiplegia, the diagnosis was reached of a tumor of the brain, and its location was thought to be in the third frontal convolution upon the left side. Although there were no evidences whatever of syphilis, it was thought best to prescribe inunctions of mercury and rapidly increasing doses of iodid of potash. This treatment was at once begun and pushed vigorously for two weeks. During this time her symptoms increased rapidly and by the 20th of December the right hemiplegia was almost complete, the aphasia was total, she could no longer read, and it was sometimes uncertain whether she fully understood what was said to her. Her speech was reduced to the words "yes" or "no," and these were not always properly used. Her headache became more and more intense, the optic neuritis increased rapidly, she was extremely restless at night, and she frequently vomited her food. It being evident, therefore, that the treatment was producing no affect, it was resolved to operate with the view of removing the tumor. The propriety of operation was concurred in by Drs. J. O'Dwyer and Callan, and by Dr. Robert F. Weir, who was called in as the consulting surgeon.

Operation, December 24, 1896, by Dr. Weir. The scalp previously having been shaved and duly disinfected, under ether anesthesia the lines of the fissures, Rolando and Sylvius, were not only marked out on the skin, but through two punctures made through the scalp to the skull over each fissure the pointed end of a disinfected pencil was rubbed on the bone beneath. This was also done over the third frontal convolution, the supposed locality of the tumor. The usual large curved flap, some three inches wide at its base, was then made and turned downward.

To control the usually free and sometimes dangerous hemorrhage from this incision, instead of clamps or a rubber band passed around the head with the temporal regions duly padded, the operator used here satisfactorily, as on several previous occasions, short hat pins, which

were passed in and out across the base of the flap itself, while around the head and projecting point of each pin was stretched one of the ordinary rubber bands of small size used for bundles, etc. Two of these pins sufficed to check the bleeding, and a similar use of these pins and rubbers along the other part of the divided scalp controlled the oozing and spurting of blood. Of course the bleeding from the bone itself had to be met, when it required attention, by the ordinary methods in use.

An inch trephine rapidly cut through a rather thin skull, and this area was enlarged with ease and promptness by means of Hoffman's rongeur forceps, until an opening two by two inches was made. This method of opening the skull was chosen as no facilities for using the electric saw with Weir's dura protector¹ were present; but in either case, the operator's preference since 1887 has been, in all cases in

FIG. 1.

The cross represents the supposed location of the tumor, the small circle the trephine opening, and the large circle the opening made by the rongeur.

which the question of a tumor arises, to leave a permanent opening in the skull to guard against either a recurrence of pressure from renewed or from another growth, or to give relief in case a growth is not found, or cannot be removed. The opening in the skull is shown in Fig. 1.

The dura was now divided about an eighth of an inch from the bone, and reflected downward in an oval flap. This procedure, the ordinary one, is not so good for a resuture as a crucial incision, but it affords a freer scope for examination of the cerebral surface. In this particular instance, in which the growth was not found, and, therefore, the pressure not relieved, considerable difficulty was experienced in closing the gap in the dura, and this was

¹ "Trans. Am. Surg. Assn.," 1897.

accomplished by inserting some gold foil¹ beneath the still gaping edges of the dura mater.

The exploration of the brain by sight and moderate palpation revealed no growth or change of circulation or nutrition. Deeper palpation, admitting the finger-end underneath the edge of the divided skull for nearly an inch in varying directions, detected no abnormality, nor did a needle meet with any resistance.

With regard to the procedure of exploring the brain for deep-lying tumors, needles or other instruments are of but little use. The finger is the best tool, and experience, as well as the tests of Adamciewicz and others, has shown that the brain will bear steady firm pressure to a great degree, if not too long continued. I have also had aid in obscure cases by opening up a convolution and making pressure at its bottom. In one instance I thus recognized, at a depth of $1\frac{1}{2}$ inches in the white substance, a tumor not otherwise to be felt.

Here, as the exploration thus carried out failed to detect the neoplasm, the operation was arrested, the dura closed in the manner already detailed, and a thin layer of

FIG. 2.

The cross shows the supposed position of the tumor, the dotted lines its real location beneath the cortex, and the radiating lines the direction of pressure exerted by the growth.

A, plane of section shown in Fig. 3.
B, plane of section shown in Fig. 4.

iodoform gauze laid over the lower half of the replaced dura, and laid out through the postero-inferior edge of the wound. The scalp flap was replaced and fastened with interrupted sutures of fine black silk, and the usual aseptic dressings applied. No improvement followed the operation.

The patient's temperature, which was 102° F. after coming out from under the influence of the ether, came down gradually to 100° F., and did not rise again. The wound healed perfectly without suppuration, the sutures being removed on the fourth day, and her pulse was quite regular and natural, but she gradually sank into a comatose condition, the hemiplegia becoming absolute and the aphasia total. During the last two days she was unable

¹ Gutta-percha tissue will answer even better than gold foil. The latter recently has been found to be penetrable by granulation-tissue, and, therefore, does not so surely prevent adhesions.

to swallow, and was comatose, and died quietly on the eighth day after the operation.

Autopsy.—A complete examination of the brain was not permitted, but an exploration through the opening in the skull was allowed. It was found that the scalp had healed perfectly, and there was no evidence whatever of pus in the dura or the brain. The process of healing with adhesions of plastic lymph had everywhere begun. On exposing the brain by laying back the dura, no special bulging was observed; its convexity was perfectly smooth. Excision of the frontal and parietal region beneath the opening failed to reveal any evidence of disease in the brain, but palpation downward revealed a considerably harder consistency of the anterior portion of the temporal lobe. This became more evident as the finger was passed into the fissure of Sylvius, and pressure downward within this fissure was made. Removal of the anterior part of the temporal lobe, including the Island of Reil, revealed the existence of a large infiltrating glioma somewhat harder

in consistency than the brain about it. This occupied the white matter of the apex and median portion of the temporal lobe infringing upon the Island of Reil and exerting pressure inward, forward, and upward. It lay about one inch beneath the cortex of the first temporal convolution and measured about one and a half inches in all directions. Microscopic examination by Dr. B. G. Briggs showed that the tumor was a glioma of considerable vascularity. In parts it was quite cellular, but not sufficiently so to be classed with the gliosarcomata. Within the tumor there were large areas of necrobiosis with small cysts and hemorrhages. The diagram shows the situation of the tumor as outlined upon the cortex and the sections show its situation within the brain.

AN ADDRESS.

THE INFLUENCE OF THE NERVOUS SYSTEM IN SKIN DISEASES.¹

BY JAMES M. WINFIELD, M.D.,

OF BROOKLYN, N. Y.;

ADJUNCT PROFESSOR OF DERMATOLOGY IN THE LONG ISLAND
COLLEGE HOSPITAL, ETC.

DERMATOLOGY is a subject of vast scope, and to be a successful cutaneous specialist the student must have considerable knowledge of general medicine. The study of this specialty will yield more profit practically, and more satisfaction scientifically, if the relations between this special class of diseases and the physiologic and pathologic conditions of other organs are thoroughly investigated and understood. The vascular, nervous, and lymphatic systems must all be studied and deductions drawn from them, for each organ of the body has more or less to do with the cause, progress, and prognosis of nearly all diseases affecting the cutaneous system. The earlier writers on dermatology taught that about all the treatment necessary was that which could be applied locally; in fact, many diseases were not treated at all, for their presence was considered beneficial to the general health. For instance, it was thought harmful to cure infantile seborrhea, or a chronic eczema affecting the legs of old people. As soon as skin diseases rose to the dignity of a special study there was a change, and thanks to the improved methods of examination, the light of advanced pathology and bacteriology, each cutaneous affection has been brought out of the obscurity which so long enshrouded it, and we are now able to understand these diseases with scientific certainty. The more we study the skin the more we are taught to recognize the great influence the nervous system has on the outbreak and course of many of its affections.

Before we consider some of the more prominent diseases traceable to disordered nerves let us glance at the physiology and anatomy of the skin. We are told that it is the external enveloping membrane of the body, giving support to the muscles and vessels beneath. It also serves as the regulator of temperature, and furthermore, protects against the introduction of infectious germs. The skin is divided into a number of layers; the one which especially interests us is that which is known as the papillary layer, situated on the free surface of the corium, consisting of numerous small, highly sensitive eminences, the papillæ. In some parts of the skin these eminences are very numerous, as for instance, in the palm of the hands and soles of the feet, while in others they are comparatively rare. Each papilla contains a papillary blood-vessel and a terminal nerve-fiber. Thus, the skin is a great sensitive envelope filled with innumerable nerve endings, which have their origin in the cerebral, spinal, and sympathetic centers. It is readily seen that in any irritation or disturbance of these ganglia the skin is made to participate, and if this irritation is continued for any

length of time the skin becomes more and more inflamed, and finally becomes thoroughly diseased.

Perhaps the most frequent neurocutaneous disturbance which the general practitioner is called upon to treat is simple acute facial erythema of the menopause, the so-called hot flashes. This is undoubtedly caused by some disturbance in the sympathetic system producing a sudden filling of the cutaneous capillaries; the inhibitory nerves to the papillæ being taken off their guard this phenomenon results. If this erythema continues for any length of time we next observe that the skin has grown thicker, and that small red lines have appeared about the nose and over the malar eminences. These are enlarged capillaries. Finally, small papulæ and pustules are seen and the condition is known as acne rosacea. This disease is not confined exclusively to females, for frequently we find it accompanying an enlarged prostate, which keeps up an irritation of the genital tract. The counterpart of this climacteric disease is simple acne, which occurs about the time of puberty. At this period of life the adolescent is passing through a wonderful change. Glands which have before been quiescent are stimulated into activity, while the nervous system is constantly in a condition of excitement. In boys there is more or less genital hypersensitiveness attendant upon the development of the sexual organs. In girls, at the beginning of menstrual life, there are frequently a number of peculiar reflex nervous phenomena, which have more or less effect on the cutaneous circulation, and this is often sufficient to cause the appearance of acne. We constantly hear the gynecologist lament the fact that so many young women have some form of menstrual irregularity, such as dysmenorrhea, amenorrhea, etc., each being capable of producing enough nervous reflex to cause acne. In treating these diseases these facts should be borne in mind, although the reflex cause, of course, is only one of many in the production of the eruption. Insure a thorough emptying of the rectum and then see to it that constipation does not recur. Try to relieve genital irritation in the male by the use of drugs, by passage of the cold sound, as recommended by Sherwell, or by urethral injections of cold water. If menstruation is attended by pain and much discomfort, hot vaginal douches will relieve the pelvic hyperemia and thus ameliorate the acne. Be constantly on the lookout for the neurotic causes, for if they are not detected and properly treated the patient will derive but little benefit from any external application you might prescribe.

Another neurotic skin disease which will be your fortune or misfortune to treat is urticaria (hives or nettlerash). No age or sex is exempt, although it is more common in females and children. The causes are so numerous that for convenience of study they should be classified, first, into direct or local irritation of the skin, and second, into indirect or reflected irritation. Under the first head is placed bites of insects, as fleas, mosquitoes, etc. The bite of a single insect will often produce enough irritation to cause an outbreak of urticarial wheals in regions of the skin far remote from the original bite. The irritation is conveyed along the sensory nerves, causing a reflex urticaria. Indirect irritation acts chiefly through the alimen-

¹ An address delivered by request before the students of the Medical Department of Syracuse University.

tary canal, usually the stomach or upper intestinal tract, the irritation being applied to the gustatory nerves and reflected on the skin. Possibly you have seen patients who always have an outbreak of urticaria after eating certain kinds of food, such as shell-fish or strawberries. These, with many other articles of diet, are capable of producing in some people severe attacks of this disease. Medicines, such as quinin, copaiba, morphin, etc., also have a similar power. This reflected skin affection is one of the nervous phenomena observed in children troubled with intestinal worms.

Disorders of the pelvic organs are frequently accompanied by urticaria, some women having attacks just before the menstrual period, or during pregnancy or lactation. I am attending a patient at present who has an urticaria arising from disordered genital organs. She is about forty-seven years of age, married, has never had any children, and for many years has been afflicted with various reflex and direct nervous troubles, all of which have been referred to the sexual tract. This attack of urticaria has existed for eight months, and began at the cessation of menstrual life. Urticaria is also seen in diseases of the nervous system, as locomotor ataxia. Some years ago Charcot reported a case of locomotor ataxia accompanied by a severe outbreak of giant urticaria. I remember a similar case, a man ill with posterior spinal sclerosis having all through his illness more or less urticaria, the rash being greatly aggravated when the spinal pain was severe. The mental attitude of a patient predisposes to this disease, depression and worry being sufficient to provoke an outbreak. Enough has been said to show that urticaria is primarily a vasomotor disturbance, direct or reflex, central, or peripheral. The course of events is probably this: a spasmodic contraction is followed by a paralytic dilatation of the vessels and stasis of the capillary circulation; exudation ensues, producing acute edema which lifts up the epiderm into a wheal. The treatment is apparent: give anything that will remove the reflex or direct irritation.

The influence of a deranged nervous system is seen in that common and protean disease, eczema. The eczematous patient is never in good health; he complains of being out of sorts, and there is a condition of nerve exhaustion, be it from worry or overwork, either of mind or body. I am inclined to think that the great struggle for wealth is often a cause of the eczema seen in business men of our large cities. Irritation of the alimentary canal or genital tract acting reflexly on the nerve-centers, and thus producing capillary dilation, will provoke an attack of eczema. Particularly is this true in children, for it is no uncommon thing to see an obstinate case of infantile eczema disappear almost like magic after the child's diet has been changed. The same result is observed after the loosening of a tight and adherent prepuce. Eczema has been known to occur as a sequel to neuralgia of certain nerves, and it is often associated with asthma. Frequently during the apparently successful treatment of eczema a sudden relapse occurs which often does more mischief in one hour than can be corrected by treatment in weeks. This certainly appears to be due to faulty innervation.

The fact that direct disturbance or disease of the nerves may produce disease of the skin is proven by the occurrence of zoster. Many theories have been advanced regarding its etiology. No matter how widely varied these theories may be they all point to some effect on the nerve ganglia or the nerve itself. Kaposi of Vienna is the strongest advocate of the theory of a nerve toxemia. I personally consider malaria to be an active cause, at least in those parts of the world where paludism is prevalent. The correctness of this opinion may be proved by an examination of the blood, and finding the malarial germs. I have reported a number of cases of zoster as occurring in Brooklyn in which the presence of these germs was demonstrated. The malarial plasmodium acts in a similar manner to any other toxic substance; it clogs the blood-vessels and impoverishes the blood and finally produces a form of neuritis. Arsenic has been recognized as being capable of producing zoster, on account of its action on the peripheral nerve ends. Poisoning from coal gas and carbonic oxid will also produce the same results. That zoster is a neurosis has been proved anatomically by Bærensprung, Charcot, and many others. The lesions observed are an interstitial inflammation of the posterior ganglion and a neuritis of the trunks of the nerves arising from it to supply the diseased cutaneous area. Chronic inflammations of the posterior columns of the cord have produced zoster while the ganglia and nerves were unaffected. In addition to inflammations producing neuritis, attacks of zoster often follow injuries about the exit of the nerves from their bony canal; as, for instance, pressure from blood clots, embolism, the presence of tumors and leprosy deposits.

Of all the ills that flesh is heir to there is probably no sensation so excruciating as itching when it becomes a disease. The dermatologist is often called upon to treat an affection known as pruritus. This is a functional defect in innervation, in which itching is the only direct symptom. Prurigo, an entirely different disease, is often confused with pruritus, but the former is a chronic inflammatory disease while the latter has no inflammatory objective symptoms. Pruritus is either general or local, and for the sake of convenience it is classified according to its location. A proper understanding of its etiology is very important, for upon this depends its successful treatment. In a certain way pruritus bears a relationship to urticaria, for the same organic disturbances will produce both. Organic diseases of the uterus and irregularities of the menstrual function will often cause it. Occasionally it is associated with hysteria, the presence of vesical calculi, vegetations of the urethra, hemorrhoids or intestinal worms. Ingestion of certain medicines, as opium, will sometimes cause it. In old age, when degenerative changes are taking place, pruritus is very frequently met with. It will be seen that the causes of the affection are very similar to those of urticaria, but the effect upon the skin is altogether different. It is primarily a functional disease, one purely of sensation, and should be viewed as being due to a reflex or direct irritation of any part of the nervous system from center to periphery, it not being accompanied by any appreciable lesion of the skin nerves.

Thus far only those diseases which are common and of

frequent occurrence have been considered. Patients suffering from acne, acne rosacea, eczema, urticaria, pruritus, and herpes zoster will consult you no matter where your practice may be, for no country or station of life is immune. The better you are prepared regarding diagnosis and treatment the greater will be your influence among your *clientele*. With your permission I will pass to those neurocutaneous affections which are more or less rare, the first occurring to me being pemphigus. This disease seems to be particularly fascinating to the youthful doctor, for I have seen hospital internes find more cases of pemphigus than almost any other skin disease, in spite of the fact that it is a disease of very infrequent occurrence, particularly in the United States. Its etiology is obscure, but all observers claim it to be of neurotic origin. It frequently accompanies various nervous diseases, such as posterior spinal sclerosis, degeneration of the peripheral nerves, chronic myelitis and acute spinal meningitis. In many cases it is difficult to determine just what the nerve defect is, but it probably has an origin in the vasomotor centers, or, as Schwimmer and others teach, it may be an atrophic neurosis.

Dermatitis herpetiformis is another of the rare diseases in which the etiology is obscure, but the consensus of opinion is that mental worry and anxiety predispose to an attack. I have had a number of patients with this disease, and at least in 90 per cent. there was some shock to the nervous system before the cutaneous outbreak occurred. Worry and loss of rest probably has a predisposing etiologic influence, but this does not militate against the theory of a neurotic origin, but rather strengthens it.

In people whose systems are run down from overwork and worry we frequently observe a rather rare disease known as lichen planus, an affection characterized by the appearance of pinhead or pea-sized flat papules with planed-off, shining tops, or, if the disease is further advanced, there is a slight scaliness. In our large cities many of the victims of this disease are girls who do hard work in badly ventilated factories or workshops. The remedies are simple: tone up the nervous system, insure proper action of the skin, relieve worry, etc.

In 1874 Raynaud of Paris published a monograph on a condition known as symmetrical gangrene of the skin. Since that time the disease has been called after him and now is known as Raynaud's disease. As the former name implies, it is a gangrene symmetrically distributed over the skin, generally affecting the fingers and toes. While the pathology is not by any means clear the disease is now generally understood to be due to a spasm of the arterioles, though whether this spasmodic condition is of central or peripheral origin cannot be positively stated, Raynaud considered it to be central.

Leucoderma, or whitening of the skin, is generally considered to be neurotic in origin. It is commonly understood that a person having white spots on the skin is apt to have some other neurosis. Closely allied with this condition is premature grayness of the hair. Almost as far back as can be remembered cases have been reported where the blanching of the hair has been attributed to sudden and severe nerve shock. The historic case of

Marie Antoinette is perhaps familiar to you all. Her hair is said to have turned gray in a night.

It is unfortunate that the subject of alopecia has to be gone into at all, as there is so much discussion and argument regarding this disease. Many good observers contend that there is only one cause, namely, nerve interference, while others equally well versed in dermatologic etiology claim that the sudden falling out of the hair in patches is undoubtedly due to the presence of some parasite, probably some form of the trichophyton. I will not attempt to prove or disprove the correctness of either theory, for there are plenty of cases which show that at least certain forms of the trouble are of trophoneurotic origin. Crocker, in his admirable work on skin diseases, classifies this disease in four distinct forms: First, universal cases developing rapidly and not necessarily in patches; second, cases in which one or more patches occur over the course of a nerve or the site of an old injury; third, in which small depressed atrophic spots occur (Neumann's alopecia circumscripta); and, fourth, parasitic cases. The first three he declares to be of neurotic origin. Universal alopecia frequently follows fright or a fall upon the head, and it is no uncommon thing to see bald patches after injury of the nerves about the head.

I have rapidly given you a short list of those diseases which we believe to be of neurotic origin. There are many others in which this etiologic factor is more uncertain, but for fear of tiring you I will refrain from going more deeply into the subject. From what has already been said, I trust that you may be able to glean some few grains of useful knowledge, so that when you have a difficult and obstinate case of skin disease to treat you will be on the alert to find out the workings of all the organs in the body, and particularly of the nervous system, always remembering that the cause of the cutaneous outbreak may be far remote from the site of the disease. When you have learned to do this, dermatology will cease to be a difficult study, and you will wonder why you ever thought it uninteresting and obscure.

MEDICAL PROGRESS.

Tuberculosis of the Spinal Cord.—SCHLESINGER (*Deut. Zeit. für Nervenheilkunde*, Bd. viii, Hft. 5 and 6) describes an interesting case of solitary tubercle occurring in the cervical cord. A healthy man was suddenly attacked with dizziness and pain, and difficulty in swallowing, symptoms which in great measure disappeared to return later in the disease with greater severity. There was disturbance of temperature sense, and shooting pains in the face, back of the head, and arms. The sense of touch and pain remained undisturbed, but that of muscular position was partly lost. As the disease progressed, atrophy of the muscles of the right hand and arm, and to a less extent, those of the left, developed, and there was stiffness of the neck with tenderness. The autopsy showed a fully developed tubercle in the cervical cord, covered in front and at the sides by a very thin layer of white matter, while behind, it was in places directly in contact with

the membranes. The gray substance of the cord was completely atrophied.

This is not the usual form in which tuberculosis of the cord manifests itself; more common is the symptom complex known as Brown-Sequard's, or a simple hemiplegia, or a complete transverse lesion of the cord. The symptoms here described are those of destruction of the gray matter, and the case may therefore properly be called "central tuberculosis." These central symptoms are often seen in spondilitis and in gliomata, conditions usually accompanied by remissions that are absent in tuberculosis.

The Origin of "Ascending" Suppurative Pyelonephritis.—

BAZY (*Centralbl. für Chirurgie*, May 8, 1897) is of the opinion that in most, if not all, instances of suppuration of the kidney and its pelvis, even the so-called "ascending" pyelonephritis, the infection is derived through the blood-vessels and not through the ureters. Experiments show that the introduction into the pelvis of the kidney of pathogenic microbes is not sufficient in itself to set up suppuration. There must also be as a predisposing cause, a kinking or compression of the ureter sufficient to produce a backing up of the urine. This explains why suppuration so often occurs in a single kidney.

A New Method of Suturing.—In the *Centralbl. für Gynäkologie*, May 15, 1897, ZWEIFEL describes a new method of applying a continuous suture which possesses the very great advantages of simplicity and rapidity of application. It is the stitch used on many "double-thread" sewing-machines, and is applied in the follow manner:

A straight blunt-pointed needle and the curved needle in a handle with an eye in its point (Peaslee) are both threaded and the threads fastened at one end of the line of suture. The Peaslee needle is then thrust through both edges of the cut, and the straight needle is each time passed through the loop in the eye of the curved one, and so a continuous suture is made, there being on each side of the incision a thread, while the crossings of the thread are all concealed.

In places where the skin is thin, this is of advantage, as it causes the fold to rise slightly in the middle; but in thick or fat skins this rise separates the epithelial edges too far, and then an extra precaution is necessary; either a turn of the thread in the straight needle must be made about the other before each stitch is taken, or a third thread is employed, which must be passed from one side to the other of the cut each time before the suture is passed through the skin. This keeps the edges flat.

A Prolonged Case of Diphtheria.—JESSEN (*Centralbl. für Inn. Med.*, May 15, 1897) reports a case of diphtheria that was unusual by reason of the length of time the disease persisted. The attack began, in a girl aged nineteen, by symptoms of general infection, and a facial erysipelas of a mild type. On the fourth day there appeared a typical ulceration on the right side of the throat, the cultures from which contained virulent diphtheria bacilli. From its starting point the membrane spread to the nasopharynx, the other side of the throat, and to the nose, while all attempts to stop it by the use of Behring's serum, as well as

by the best known local applications, were failures. Paralysis of the palate followed four weeks after the beginning of the illness. Lactic acid was efficacious in removing the membrane, which, however, quickly reappeared. Mild gargles, as of salt water, seemed to be of most service. The secretion was tested at numerous times during the continuance of the trouble, and it was invariably found to contain Löffler's bacilli. Clinical evidences of the disease persisted for more than five months.

THERAPEUTIC NOTES.

Treatment of Wounds with an Ointment of Yellow Oxid of Mercury.—MAJEWSKI of Prezemysl has for some time used as a dressing for wounds an ointment containing one part of yellow oxid of mercury and three parts of vaselin. This ointment possesses a very powerful antiseptic action and rapidly stops all purulent processes and promotes granulations. The skin is washed with soap, and then with ether or turpentine. The wound is cleansed with normal salt solution, and if it is deep is filled with corrosive sublimate gauze. Over this is laid a piece of gauze, spread with the oxid ointment, of the exact size of the wound. In this way all danger of intoxication from absorption of the ointment is avoided. The dressing is discontinued after five or six days in order to avoid too great stimulation of the granulating surface.

By the use of this method of treatment, Majewski was able in ten days to sew up an abscess cavity which at the time of incision contained over sixteen ounces of bloody pus. Six days after the suture the stitches were removed, the wound being completely healed. In the beginning of this treatment a patient occasionally developed mercurial eczema, or salivation, or diarrhea, but there were no severe cases of poisoning. These accidents were all due to the fact that the ointment was allowed to come in contact with the skin.

Vibratory Massage in Cardiac Palpitation.—The good effects of rhythmic vibrations upon nerves, muscles, and upon both local and general circulation are well known. Recently BAHR (*La Semaine Méd.*, May 19, 1897) has employed them with success in a case of tachycardia. The patient in question suffered from mitral insufficiency which was well compensated, but produced violent palpitation at times. Bahr saw him in one of these attacks, when the feeling of oppression was intense and the pulse was beating 140 times a minute. By means of the palm of the hand laid flat upon the cardiac region, a series of rhythmic compressions was administered to the thorax. Under the influence of this maneuver, the number of pulsations fell rapidly to sixty-eight per minute and all the subjective symptoms rapidly disappeared.

Treatment of Polyneuritis in Acute Rheumatism.—In the course of acute articular rheumatism patients often complain of spontaneous pains simulating a new joint affection. Examination will show, however, that no signs of inflammation of the joints are present, but that the pain corresponds in its location to some nerve trunk, which is

also sensitive to pressure. In other words, there is a polyneuritis complicating the rheumatism.

For this condition STEINER (*La Presse Méd.*, May 29, 1897) recommends the following prescription:

℞ Salicylate of soda	3 i
Iodid of potash	gr. xii-xxiv
Water	℥ vi.

M. Sig. To be taken in divided doses during the day.

Quinin in Incomplete Abortion.—SCHWAB (*La Semaine Méd.*, April 28, 1897), in incomplete abortion, has seen very good results follow the administration of two doses of quinin, each of eight grains, and taken fifteen minutes apart. Ergot was formerly much used to stimulate uterine contractions, but on account of many unpleasant complications it has been abandoned in abortion. Quinin is equally valuable in stimulating the uterine muscle and does not produce a tetanization, so that there is no danger of retention of the placenta. In fact, Schwab has employed it in severe cases of post-abortive retained placenta, and in every case the placenta was expelled after a period averaging four-hours and a half.

As the use of quinin in this dose (sixteen grains) is absolutely devoid of danger, it seems advisable to employ it in all cases of delayed abortion when there is no especial reason for immediate operation, for if it fails operation can then be resorted to.

Hydrastis Canadensis in Bronchitis.—SAENGER (*Centralbl. f. inn. Medicine*, May 1, 1897) has found hydrastis canadensis an excellent remedy in certain forms of chronic bronchitis. In the beginning of an attack it has little effect, but later, when the mucous expectoration has become mucopurulent in character, the effect of its administration is striking, as it lessens the tendency to cough, loosens the expectoration, and makes the secretion of the bronchial mucous membrane thinner, and changes its character from a purulent or mucopurulent to a mucous one. It also causes most of the physical signs of bronchitis to disappear. The effect of hydrastis is more lasting than that of opium, and its expectorant action is at least as great as that of the expectorants in common use. Senger gives only the fluid extract in doses of from twenty to thirty drops four times daily.

A Resorcin Salve for Acne.—EHRMANN (*Ther. Wochenschr.*, May 9, 1897) recommends in acne, abdominal massage, cascara sagrada, Carlsbad salts, etc., to regulate the intestinal action. For a local application, and one which fulfils the double requirements of preventing the stopping up of the sebaceous follicles and of disinfecting without irritating the skin, he uses a fifteen-per-cent. resorcin salve, which should be made thick, *e. g.*:

℞ Resorcin	3 parts
Lanolin	15 parts
Simple ointment	5 parts.

The salve should be left for fifteen hours on the skin and then be washed off with a mild soap.

After a time the skin peels off, and the treatment with resorcin must be omitted and a simple salve substituted for a few days. Pimples should be incised, and if they are superficial the contents may sometimes be extracted with a mouse-toothed forceps. If too deep for this, or in the

early stages after incision and evacuation of the contents, a drop of twenty-per-cent. solution of carbolic acid in alcohol should be inserted to prevent further development of bacteria.

Treatment of Congenital Hernia in Children with Injections of Chlorid of Zinc.—LANNELONGUE (*Ther. Wochenschr.*, April 25, 1897) has for the past six months made use of a ten-per-cent. solution of chlorid of zinc in order to obliterate the inguinal canal in cases of congenital hernia in children. The technic is very simple. Naturally, aseptic precautions are observed. After the reduction of the hernia an assistant, by the pressure of his finger, closes the communication between the hernial sac and the peritoneal cavity. The operator locates the spermatic cord and holds it with one finger to the outer side. On the inner side, beginning at the upper end of the canal, injections of five or six drops each of the zinc solution are made in four places along the length of the canal. The cord is now slipped to the inner side, and four more injections are made to the outer side of the canal. A compress now takes the place of the assistant's finger, and is held in position with a Spica bandage. The whole procedure occupies only two or three minutes. It is without danger, and thus far has given satisfactory results in Lannelongue's hands.

Milk and Eggs in Typhoid Fever.—In the *Charlotte Medical Journal* for May, 1897, ELY speaks of the dietetic treatment of typhoid fever. He has found no food which he considers preferable to milk, either plain, boiled, peptonized, or with lime water or soda, according to indications. Two quarts a day is the minimum amount given, and no distinction is made between night and day. In some cases an amount of milk which, given every three hours, would be rejected, can be retained if given in divided portions every hour or every half hour, or if need be, every fifteen minutes. Milk may be supplemented by beef juice or eggs. Of the latter he has sometimes given with benefit twenty whole or the whites of forty per day.

Benzoate of Mercury.—The benzoate of mercury is a soluble salt, not only in water, but also in alkaline solutions of a chlorid, or an iodid. The following preparation is the one most employed by GAUCHER:

℞ Benzoate of mercury	gr. 4
Hydrochlorate of cocain }	gr. 1
Chlorid of sodium } aa	
Sterilized water	℥ 1.

For hypodermic use, fifteen minims per day for one week; then two minims per day. The cocain may be omitted without any unpleasant effects, as the pain of injection is not worth considering.

The Proper Temperature of Milk for the Baby.—SMESTER (*La Presse Méd.*, May 22, 1897) has found the temperature of milk as drawn from the breast to be about the same as that of the surface of the body, that is 97° to 98° F. He, therefore, says that the milk in a baby's bottle should not exceed this temperature, and, if anything, should be even a little below this point. He claims to have observed that a baby will take with evident repugnance, milk which is slightly above 97°.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor : J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, AUGUST 7, 1897.

HYDROPHOBIA AND RABIES.

THE time is now upon us when the sun enters the constellation of the Great Dog (*Canis Major*), and is nearly in conjunction with the dog-star Sirius. These days, popularly known as "dog days," have become more or less associated in the public mind with the prevalence of hydrophobia. This idea is so universal, and has been stimulated so much of late by the attention drawn to rabies through the researches of Pasteur and his disciples, that many people regard with horror the approach of a dog during this season, and the entire civilized world is in such a state of nervous excitement in regard to the malady that the slightest scratch upon the skin made by the teeth of a dog, whether he be afflicted with rabies or not, is very apt to cause the person so wounded to present all the characteristic symptoms of hydrophobia.

The sensitiveness of the public to this popular notion, and the harm that it does to both man and beast, have been pointed out in the July issue of *Our Animal Friends* by Mr. John P. Haines, president of the New York Society for the Prevention of Cruelty to Animals. In his commendable efforts to reassure the public, Mr. Haines has rather overdone the mat-

ter. He fails to appreciate entirely the scientific character of Pasteur's researches, and casts a suspicion upon all his work in this field. This is to be deprecated and regretted, for, aside from this, the article is based upon good authority, and is calculated to do much good.

First of all, Mr. Haines points out that hydrophobia¹ is one of the rarest diseases with which humanity is afflicted; that rabies is one of the rarest diseases of the dog, and is no more likely to occur in July or August than in December or January. In confirmation of the former statement, the writer asserts that during the thirty years of the existence of the American S. P. C. A., there has been recorded upon its books no well-established case of rabies, either in dog or man.

The rarity of rabies is confirmed by the best medical authorities. Biggs, in writing upon this subject in Dennis' "System of Surgery," asserts that under all conditions rabies is a comparatively rare disease in man. In New York during the ten years ending 1891, there were only nine deaths reported to the Health Department as being due to rabies. There is no statement as to whether the report was verified or not.

Dercum ("Nervous Diseases by American Authors") says that "hydrophobia is a rare disease in the United States. Dulles, from June 1, 1888, to January 1, 1894, collected seventy-eight cases, an average of fourteen *per annum*. But after investigation, Dulles is said to have pronounced the great majority of these cases utterly incredible and wholly spurious."

Gray ("Nervous Diseases") declares there is not a neurologist in New York City who has seen in his practice more than one case of hydrophobia, and it is well known that Spitzka, Brell, Stockwell, and others, besides those already mentioned, entertain a strong feeling of skepticism regarding the pathologic entity of such a disease.

How then shall we account for the frequent reports of cases of rabies? In the first place every dog which happens to be suffering from any disease whatever during the dog-days is at once set down as "mad." As Mr. Haines says, a frightened dog, cruelly pursued by thoughtless children with the cry of "mad dog," is regarded with terror, and any

¹ It would be well to drop this word from medical nomenclature. Rabies is the same disease in man and dog, and should have the same name. "Hydrophobia" is founded on an entire misconception.

report of a case of rabies, however ill founded it may be, is at once communicated to the newspapers, and through them spreads consternation to hundreds of nervous people.

It must be remembered, as has been said, that rabies in a dog is an extremely rare disease. Probably not one dog in a thousand which is thought to be mad is really afflicted with the malady. It is important that not only the profession but the laity should understand that all dogs perspire excessively through the glands of the mucous membrane of the mouth and tongue during the hot weather. If a dog has been running, this perspiration may even be lapped into froth, and the dog may be said to be "foaming at the mouth." This, however, does not constitute rabies. In rabies, the secretions of these glands become pathologic, and the discharge from the mouth is thick, tenacious, and ropy, and in order to disengage it from his mouth, the dog frequently tears at it with his claws.

In order that some definite scientific data may be obtained for determining the frequency of rabies in dogs, and upon which to base the probability of injuries, received from dogs, developing rabies in man, the New York Board of Health, as was pointed out in a recent issue of *THE NEWS*, has provided for investigation of every case of supposed rabies reported in the city. Arrangement has been made by it through the police department for securing and taking to its laboratory every animal which may be supposed to be suffering from rabies. A thorough investigation will then be made through inoculation of rabbits, guinea-pigs, etc. Such careful research will relieve the victim of a scratch or bite of a dog of the terrifying apprehension which invariably hangs over him till he is assured of the healthfulness of the dog, or guarantee to him proper treatment if it becomes certain that the animal was afflicted with the malady.

The long period of incubation of rabies keeps the nerves of the victim of a dog bite in a state of supreme tension for so long a period that he not infrequently succumbs to nervous exhaustion and experiences all the phenomena of the disease as a case of pseudo-rabies, or lyssophobia.

"A nervous person bitten by a dog, either rabid or supposed to be so, may display within a few months, or even several years afterward, symptoms resembling hydrophobia. There have been instances

published, as lyssophobia, in which seizures have become frequent, and the patient has died exhausted. Dulles has called attention to a number of diseases in which symptoms of hydrophobia may occur, and he has rightly urged a more thorough and systematic examination of patients, and a greater caution in pronouncing upon the irregular symptoms which, in nervous people, are apt to follow the bite of a dog." (Dercum.)

Biggs says numerous cases have been reported in which patients apparently suffering from true rabies suddenly recovered when the animal by which they were bitten appeared before them well, or when they were convinced in some other way that the dog had not been suffering from rabies. When we realize, also, that only fifteen per cent. of the persons wounded by a dog which is known to be rabid suffer from the disease, the probability of infection becomes still less. It is safe, therefore, to accept the conclusions of the lay writer above referred to, when he says:

"Remember these points: (1) There are more than a million of chances to one that any dog which is supposed to be mad is not mad at all. (2) In all probability any dog by which a person may happen to be bitten is not mad; and (3) even if a person is bitten by a dog which really is mad, the danger of hydrophobia is very slight indeed."

ECHOES AND NEWS.

Course of Study Extended.—The Medico-Chirurgical College of Philadelphia has extended its course of study to four years.

An Eighteen-Pound Baby.—A woman at Fishkill Landing, N. Y., has recently given birth to a baby girl weighing eighteen pounds.

Indian Mails Disinfected.—The steamer "Majestic," which recently arrived at the port of New York, carried thirteen bags of mail from Bombay. This will be thoroughly disinfected before it is distributed.

Swallowed Tooth-filling.—At Middletown, N. Y., a man recently swallowed a gold filling which had fallen out of a tooth. The man is now seriously ill with appendicitis as a result, it is claimed, of the accident.

The Jubilee of "Le Scalpel."—This well known medical journal, which is published at Liege, Belgium, and was founded by the late Dr. Festraerts, has recently completed the fiftieth year of its existence.

The Plague and the Vultures.—Since the plague made its appearance in India there has been an enormous increase

in the number of vultures, which devour the bodies of the dead consigned to the "Towers of Silence."

The Murphy Button in Germany.—It would seem that the Murphy button is quite extensively used in Germany. Czerny not long ago reported to the German Surgical Society fifty-five recent cases in which the button was employed.

Consumptives in the Southwest.—It is reported that in El Paso, Texas, there is a growing sentiment against consumptives flocking to the Southwest, and the desire for sanitary measures against the disease is rapidly gaining ground.

Smallpox in Montreal.—It is reported that five cases of smallpox have been discovered in Montreal. The cases are scattered about over the city and cannot be traced to any common origin. Vaccination is being carried on extensively.

British Surgery in America.—Mr. Christopher Heath, late President of the Royal College of Surgeons, England, has accepted the invitation to deliver the second course of Lane Medical Lectures at the Cooper Medical College, San Francisco.

Hospital Salaries Reduced.—It is reported that a twenty-per-cent. reduction in the salaries of many of the employees of Bellevue Hospital was made on August 1st. It is claimed that the appropriation is insufficient to meet present demands.

Sunstrokes in New Orleans.—It is said that a large number of sunstrokes occurred in New Orleans during the June hot wave, and that more than half of the cases proved fatal. This is surprising because, as a rule, sunstroke is rare in that city.

Another Case of Hiccoughs.—In the Cook County Hospital, Chicago, there is a case of hiccoughs which it is feared will prove fatal. The patient is a man, seventy-four years of age, who for ten years has been subject to periodic attacks of hiccough.

Death of Professor Schutzenberger.—The eminent chemist, Professor Schutzenberger, is dead. He was born at Strasburg, and studied medicine there. He became Professor of Chemistry at the College de France in 1876, and was the author of many works on chemistry.

A Pension for M. Henri Dunant.—The Russian branch of the Red Cross Society has granted a pension of a thousand roubles annually to M. Henri Dunant, of Geneva, whose name is well-known in connection with the foundation of that Society, and who is in greatly reduced circumstances.

X-Rays Applied to Mining.—Dr. F. E. Yoakum of Los Angeles, Cal., has applied the X-ray in determining the presence of gold in quartz. He has taken a number of pictures showing gold in ore, the fluoroscope being used for the purpose. It is believed that the discovery will be of use to geologists and mineralogists in prospecting.

Dr. Ohlmacher to Investigate the Etiology of Epilepsy.—Dr. A. P. Ohlmacher of the Cleveland College of Physicians and Surgeons has assumed direction of the pathological laboratory of the Ohio Hospital for Epileptics at Gallipolis in that State, where it is proposed to make investigations bearing upon the etiology and pathology of epilepsy.

Afraid of Appendicitis.—In Wayne County, N. Y., several cases of appendicitis which have occurred there have been attributed to berry seeds. Consequently berries are a drug in the market. Housewives refrain from preserving raspberries and blackberries, and farmers are forced to evaporate their berries or convert them into wine.

A Woman Physician for Mohammedan Women.—Dr. Theodora Krayewska, a Pole by birth, is the first woman appointed to attend Mohammedan women in Bosnia, which is under Austrian rule. The appointment comes under the head of army surgeons, therefore she is obliged to wear a uniform. Her rank is equal to that of a captain, and her salary the same.

Mississippi Valley Medical Association.—The next meeting of this Association will be held at Louisville, Ky., October 5, 6, 7 and 8, 1897. The address on Surgery will be delivered by Dr. J. B. Murphy, of Chicago; the address on Medicine by Dr. John V. Shoemaker, of Philadelphia. The title of papers should be sent to Dr. H. W. Loeb, secretary, St. Louis, Mo.

Delegates to the International Congress.—Sixty Mexican physicians, on their way to the International Medical Congress at Moscow, were booked to sail on the steamship Normannia on July 29th. That vessel was not able to sail on account of a flaw which was discovered in her shaft, and her passengers were transferred to another steamship which sailed on the following day.

Infected Rabbits at Large.—The news comes from Paris that a number of rabbits have been stolen from a hospital where they were being used in the culture of germs of cholera, diphtheria, the plague, and other diseases. It is feared that the rabbits will be sold for food, but the bacteriologists announce that even if the rabbits are eaten there is no danger if their flesh is well cooked.

Johns Hopkins Loses a Part of Its Income.—The news comes from Baltimore that a decision was handed down in the United States Circuit Court by Judge Goff, by which the Johns Hopkins University and other holders of Baltimore and Ohio stock are declared not preferred creditors. If this decision is upheld in the Supreme Court, the University will lose about \$50,000 of its annual income.

Eudoxine.—In the article by Dr. Reynold W. Wilcox, entitled "The Newer Preparations of Bismuth," which appeared in the issue of THE MEDICAL NEWS of July 31st, by a typographical error the preparation chemically known as tetra-iodo-phenol-phthalein was referred to as *endoxine*, instead of eudoxine, a well-known gastro-intestinal anti-

septic placed upon the market in this country by Messrs. Stallman & Fulton.

Typhus Fever at Pekin.—According to the lately issued volume of the Medical Reports of the Imperial Maritime Customs, China, typhus fever is epidemic at Pekin in the spring of each year. The mortality, although considerable, is not so great as that from cholera. The volume also contains an essay upon typhus fever by Dr. Matignon of the French Legation at Pekin, who has made a most careful and thorough study of the disease.

Wears Gloves When He Operates.—Professor J. Mikulicz now wears gloves when he operates, because he believes it is impossible to render the hands perfectly aseptic. The gloves are of cotton and can be washed and boiled and repeatedly used. If the operation is short and aseptic, one pair of gloves is sufficient; if not, he changes them two or three times. His assistants also wear the gloves. The use of rubber gloves by the surgeons of New York and their assistants is a very common practice.

Occupations in America.—According to the bulletin of the Eleventh Census, the total number of people engaged in occupations of all kinds in 1890 was 22,735,661. Females form 17.22 per cent. of this number. Professors and teachers, of whom there are 347,344, form the largest professional class; physicians and surgeons, 104,805, are next in number; then come lawyers, 89,630; clergymen, 88,203; government officials, 79,664; musicians, etc., 62,155; engineers and surveyors, 43,239; artists and art teachers, 22,496; journalists, 21,849, and actors, 9,728.

Reading and Eye-fatigue.—The *Medical Press* points out the fact that the size of the printed characters is a more important factor in the production of visual fatigue than any other, and the conclusion arrived at is that type less than 1.5 millimeters in height should not be employed. The degree of illumination, so far as concerns daylight in fairly lighted rooms, is of much less importance, although deficient illumination, especially when the source is an artificial light, will, under certain circumstances, induce visual fatigue more rapidly even than small type. Whenever artificial light is employed, a white light is said to be preferable to a yellow light, contrary to general opinion.

Hams and Hairs.—A case was recently tried in Birmingham, Eng., to decide whether a ham which was offered for sale as an English ham was really what it was represented to be. A point in the case was that the ham in question bore three hairs growing from a single root, and this was put forward as evidence that the ham must be American. It was shown by the defence, however, that three hairs growing from one root is a characteristic of the Berkshire breed of pigs, although not entirely confined to these. As the "three-hairs" proof was the only evidence offered to show that the ham was American, this was considered too weak a support, and the case was dismissed.

Burned by Roentgen Rays.—An unusual case of burning by the X-rays recently has been reported. A young

woman consulted a dentist on account of pain in the upper jaw. As nothing was found there to explain the symptoms, the trouble was supposed to be in the antrum, and she was advised to have a skiagraph taken in order to clear up the diagnosis. This was done, two exposures being necessary, the first lasting about eight minutes, the second thirteen. There were no signs of any ill effects until two days later, at which time the woman's face began to swell, blisters then appeared on the face, neck, shoulder, and arm, and the hair on that side of the head came out, leaving one half of the scalp perfectly bald.

The Faculty of the Southwestern Medical School.—The faculty, as far as elected, of the newly organized Southwestern Medical School of Texas, is as follows: J. M. Pace, M.D., professor of clinical medicine and diseases of children, and president of the faculty; S. H. Stout, M.D., professor of obstetrics; C. M. Rosser, M.D., professor of theory and practice of medicine; H. K. Leake, M.D., professor of diseases of women; C. H. Sherman, M.D., professor of anatomy; S. E. Milliken, M.D., professor of general and orthopedic surgery; H. L. McLaurin, M.D., professor of materia medica and therapeutics; R. H. Chilton, M.D., professor of ophthalmology and otology; L. Myers Connor, Ph.G., professor of chemistry; Hon. Dudley G. Wooten, lecturer on medical jurisprudence.

Medical Schools in Denver.—The Supreme Court of the State of Colorado has forbidden the University of Colorado from carrying on any part of its Medical Department in Denver, because the constitution locates the University itself at Boulder. In consequence of this, the members of the Faculty resident in Denver have resigned, and the larger portion of them have united with the Medical Department of the University of Denver. Among those who have thus strengthened the Denver Medical School are: Drs. H. T. Pershing in Diseases of the Mind and Nervous System, S. G. Bonney and H. B. Whitney in Medicine, Charles A. Powers in Surgery, Walter A. Jayne in Gynecology, George B. Packard in Orthopedics, L. E. Lemen and J. W. O'Connor in Clinical Surgery, T. E. Taylor in Clinical Obstetrics, and John Chase in Clinical Ophthalmology. The Faculty of the School has been further enlarged by the election of Drs. P. V. Carlin in Obstetrics, W. H. Bergtold and W. B. Fenn in Pathology, and Carroll E. Edson in Therapeutics.

CORRESPONDENCE.

A FURTHER WORD FROM DR. LEFFINGWELL.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS of July 24th I find what purports to be "a reply to Dr. Leffingwell." The privilege of reply by a person unaddressed is rather a matter of favor than right; and the letter you did me the honor to print was intended only for the consideration of my professional brethren, and not for veterinary experts, however eminent in sciences pertaining to agriculture. Your correspondent would imply doubts as to my

acquaintance with our mother-tongue; I shall not question his own evident familiarity with a vigorous vernacular, which has its place,—but that place is not in the consulting-room of medical men. Any formal rejoinder I do not care to make; but one or two points in his letter are so imbued with inaccuracy that I should like to refer to them.

"Is not the British bill sufficiently harassing and destructive to experimental research?" asks your learned correspondent, in a question that insinuates its own reply. I suppose no impression is more widely diffused among medical men in this country than the detrimental effects of the English law: Professor Bowditch of Harvard Medical School stated in his letter to Senator Gallinger that it had "inflicted a serious blow upon English physiology." Is this true? Who should know best—the opponents to all legislation in this country, or the medical men in England who have worked under this law for the last twenty years? I presume the *British Medical Journal* will be taken as a pretty good authority. In an article on "Physiology," which appeared in its issue for June 19, 1897,—not six weeks since—the writer says: "Though we have a Vivisection Act in operation, but few physiologists have had cause to grumble on this score, for the act has been administered by successive Home Secretaries with wisdom and fairness." (p. 1541.) Where is the complaint of serious injury here? But there is other evidence. In a letter I received not long ago from Sir John Eric Erichsen, the eminent surgeon, after stating that vivisections should not be allowed without proper restrictions, he adds: "Experiments on living animals are most carefully restricted in this country. . . . I acted as government inspector for several years, and I can safely assert that the provisions of the act were vigorously enforced, and never to my knowledge contravened." Can it be supposed that if the English law had worked such injury to medical science as some would have us believe, that no reference to such an effect would have been made? Of course the law has been unsatisfactory to some. It has hindered and prevented repetition on English soil of the atrocities which the late Dr. John C. Dalton—a physiologist of no mean repute—tells us that he saw in a veterinary institution on the Continent, than which, he says, "nothing could be more shocking;" it has prevented those abuses of vivisection that the same eminent authority tells us have been done "by reckless, unfeeling, or unskilful persons;" it has hindered the free hand of men referred to by Dr. Theophilus Parvin of Jefferson Medical College in his presidential address before the American Academy of Medicine lately, "who seem, seeking useless knowledge, to be blind to the writhing agony of their victims, and who have been guilty of the most damnable cruelties." I do not know to whom Dr. Parvin alluded when he affirmed that "these criminals are not confined to Germany or France, . . . but may be found in our own country;" but I am sure that wherever they are, they join with your correspondent in affirming that "no one can tell whose method of investigation is right or wrong," and that "research should be free." But there are some of us who believe in vivi-

section for any purpose of good to humanity, but not in vivisection like that which prevails abroad, and which many of us have seen. "After the furtherance of science, the saving of human life is the noblest object we have in view," says a recent writer, referring to vivisection. I cannot but think that it will be a sad day for the human race, if ever that shall become the universal ideal of the medical profession.

Regarding the effect of the proposed legislation at Washington in impeding any phase of useful experimentation, I may say that Senator Gallinger—himself a physician (which your correspondent is not)—denies that the law is capable of the construction or of the effect outlined by its opponents in the Department of Agriculture. Here is a difference of opinion; but as between the veterinarian and the physician—one opposing any law whatever and the other an experienced legislator—I prefer the judgment of the medical man.

May I refer to one point in your courteous reply to my letter in THE MEDICAL NEWS? Legislation, you say, is being urged by persons "who have become excited by reading the antivivisection literature sent them by Dr. Leffingwell," etc. This is a mistake. I have never circulated "antivivisection literature;" nor, since July, 1880,—seventeen years ago,—when my first article in advocacy of State supervision appeared in *Scribner's Magazine*, have I ever written a line antagonistic to vivisection when kept in proper hands and surrounded by adequate restrictions against abuse.

ALBERT LEFFINGWELL, M.D.

BROOKLYN, JULY 27, 1897.

[Dr. Leffingwell's quotation from the *British Medical Journal* is convincing as far as it goes, but the paragraph carries an entirely different impression when read in its entirety, as follows:

"There are at present signs that England will not be far behind Germany, or may even take the lead in the future. The antivivisection movement in this country, with which physiologists have had to grapple, has had some share in retarding the progress of physiology here. To-day, though we have a vivisection act in operation, but few physiologists have had cause to grumble on this score, for the Act has been administered by successive Home Secretaries with wisdom and fairness. To-day, also, we can hardly doubt that the antivivisectionists, though a noisy section, constitute a very small section of the public. The discovery of anesthetics, the jubilee of which is only just over, has robbed experiments on animals of the terrors they formerly possessed." The extreme attitude of the antivivisectionist element was exemplified by a bill which they presented to Parliament, and which, according to a writer in the *British Medical Journal* of the same date, "would probably have completely stopped the carrying out of physiological investigations in England."

This entire discussion in regard to the bill before Congress regulating animal experimentation in the District of Columbia resolves itself into this, namely: No cruelty has been discovered in any of the laboratories of the District;

the present law is sufficient to prevent any cruelty, therefore the enactment of the proposed law is unnecessary.—EDITOR.]

THE ALLEGED MICROSCOPIC POWER OF THE NORMAL EYE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In the *Medical Record* of January 23, 1897, page 119, Dr. F. L. O. Roehrig of Pasadena, Cal., published an article, entitled "Microscopical Power of the Natural Normal Eye," an article which we should not indifferently allow to pass unnoticed, not because it may "gradually lead to perhaps many as yet wholly unexpected important scientific truths and various valuable new discoveries," but because it is apt to convey confusion and erroneous conceptions of a phenomenon which has been long and well understood.

Dr. Roehrig, when he looked at his mustache at a distance of an inch or two, more or less, saw every hair greatly magnified, just as seen through a microscope. Each hair stood out plainly and distinctly and as though forming a tube, which, according to all appearance, was transparent, rather colorless, hollow, and empty, bounded, as it were, on both sides by a generally well-marked bright white line or border. The size of the magnified hair-tubes varied from that of an ordinary darning-needle to the volume of a small lead-pencil; it increased gradually in proportion as he moved these tubes slowly upward from the chin, and it seemed to reach its maximum when seen nearly high enough to be somewhat on a level with the eye.

The explanation of the phenomenon rests in the fact that the eye cannot accommodate at a smaller distance than that of the near point, which requires the maximum of accommodation. Dr. Roehrig looked at the hairs at a distance of an inch or two, more or less. The near point (*punctum proximum*), *i.e.*, the nearest point of distinct vision, in normal eyes lies, according to Donders, at the age of ten years at 2.8 inches from the eye; at twenty years, 4 inches; at thirty years, 5.7 inches; at forty years, 8.88 inches; at fifty years, 16 inches, etc. Light emanating from each point of an object placed at the distance of the near point, after passing through the pupil, forms a luminous cone with a circular base in front, which will impinge with its apex on the retina, when the eye is in the state of its maximal accommodation, and form a well-defined image of each point, and consequently of the object, so that the object is seen distinctly. If, however, the object is brought nearer to the eye (to a point to which the eye cannot accommodate), the apex of the pencil of rays will fall behind the retina. Then not a single point but a circle of the retina, corresponding to a circular section of the luminous cone, will be illuminated, *i.e.*, a *circle of diffusion*, will result, and the image will become diffused and indistinct. A hair, under these circumstances, will appear as an ill-defined dark stripe. The same may be observed not only if an object is placed nearer to the eye than the near point, but at any distance if we accommodate at a longer or shorter distance than that of the object.

The well-known Scheiner experiment very clearly illus-

trates these conditions. (*Oculus sive Fundamentum Opticum*, Innsbrück, 1619.)

If a pin held vertically toward the luminous sky is fixedly looked at through two small holes in a card not further apart than the diameter of the pupil, and placed horizontally (and *vice versa*), we see the pin distinctly. If now we fixate an object nearer or farther than the pin, the pin appears double. The same can be objectively demonstrated with a convex lens before which is placed an opaque screen with two holes. The rays proceeding from the luminous point through the holes are focused by the lens, and a piece of paper placed at the focusing point will show a well-defined image of the luminous point. If the paper is placed in front of the focus or behind it, it will receive the two small pencils of rays corresponding to each hole separately; each pencil will make its own circle of diffusion and show two images. If we substitute for the lens the refracting media of the eye, and for the piece of paper the retina, it follows that a point of the retina will be illuminated if the retina lies in the plane of the focus of the rays, but two points (*i.e.*, circles of diffusion) if it lies in front or behind the focus of the rays.

An object placed so close to the eye that the eye cannot be accommodated to it may, however, be seen distinctly if we look at it through a small hole in a card. The base of the luminous cone penetrating the eye becomes smaller, and also its sections, that is, the circles of diffusion of the retina. The object thus appears even larger than if observed in circles of diffusion at the same distance without the hole, and becomes still larger if the hole is moved away from the eye. (H. v. Helmholtz, "Handbuch der physiologischen Optik," 2 A., p. 118.)

That the state of refraction does not make any difference, except in degree and with some modifications, will readily be conceived. Therefore, it is erroneous to say, as Dr. Roehrig does, "Those, however, whose visual powers are even in the least degree vitiated by anything anomalous or abnormal, such as myopia, presbyopia, hypermetropia, astigmatism, etc., cannot reasonably be expected to possess or acquire the necessary aptitude for those microscopic perceptions." The law (of faulty accommodation) itself remains unaltered. It is only modified, that is, in astigmatism, by unsymmetrical monochromatic aberrations. The circles of diffusion of a luminous point are changed into stellate figures, the lightest points of which are multiplied images of the luminous point. A luminous line will appear in an astigmatic eye as a light stripe, in which multiple (from two to six or eight) images of the line are recognized. This is generally called *polyopia monocularis*. But even here the condition is that the eye is not accommodated to the object.

The only case in which we might speak of a magnifying (not microscopic) power of the naked eye is in very high degrees of myopia. At a distance for which a normal eye would require a magnifying lens, small objects may be seen by a myopic eye distinctly and, on account of their nearness, magnified.

Another proof that Dr. Roehrig saw the hairs in circles of diffusion is that "one or two of those tubes appeared in beautiful rainbow-like colors." The eye is

not achromatic, but as long as the image is received at the focal distance, or when it is accommodated to the distance of the object, the achromasia is ordinarily hardly noticeable, because the optic media of the eye are in their refrangibility very similar to water, the dispersion of which is much less than that of glass. If, however, the eye is not accommodated to the distance of the object, that is, when the image is formed in front or behind the retina, colored borders appear around the object from chromatic aberration. A pin held before the eye toward the sky will be seen distinctly, with proper accommodation, but if we relax the accommodation or adjust it for a smaller distance, three or more pins are visible parallel to each other, the middle one dark yellowish, and on each side of it one or more of light blue.

C. ZIMMERMANN, M.D.

MILWAUKEE, WIS., July 23, 1897.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE VIENNA BOARD OF HEALTH AND A FORM OF CONJUNCTIVITIS DUE TO THE DIPLOCOCCUS PNEUMONIE—THE OCCURRENCE OF AN INTRACELLULAR IODIN REACTION IN ACUTE SUPPURATION—THE STATUS LYMPHATICUS AND ITS CONNECTION WITH SUDDEN DEATHS IN NARCOSIS, SLIGHT ACCIDENTS, AND THE INFECTIOUS FEVERS.

VIENNA, July 17, 1897.

A notice recently served by the *Wiener Stadtphysikat* (Vienna Board of Health) on the physicians of the city gives an idea of how they do these things legally over here, and calls attention to a very interesting and only recently differentiated type of conjunctivitis:

"The attention of the board of health has recently been called to an inflammation of the conjunctiva occurring especially in school children. Its cause has been demonstrated by bacterial examination to be the diplococcus pneumoniae (Fränkel-Wexchelbaum). Its symptoms in ordinary cases are moderate catarrh of the mucous membrane, some edema, especially of the upper lids, accompanied by swelling in the semilunar folds and carunculae, with hyperemia of the conjunctiva tarsi, and of the conjunctival folds, a special bluish tint being characteristic of it in this situation. In slight cases, there is not much secretion, though there is a considerable increase of tears. In severer cases, the secretion is plentiful and rather thick and yellowish in color.

"In order to avoid confusion of the above described conjunctivitis with trachoma, and in order to assure the carrying out of the special measures required to prevent the spread of each, you are hereby notified and put legally under obligation in the event of its appearance in your practice to at once report the case to the *Stadtphysikat* in the manner required by law."

This public regulation of contagious eye diseases is all the more interesting, as it has been instituted as a result of sad experience with their ravages when unregulated in various parts of the Empire.

The rôle of the diplococcus pneumoniae is becoming more and more important, as the bacteriologic examination of affected tissues and secretions is being more sys-

tematically carried out. It would seem as though any form of inflammation of mucous or serous membranes may be caused by this almost normal member of the oral flora. Suspicion is becoming almost certainty that, in addition, it is the cause of a number of purulent affections in which the ordinary pyogenic bacteria are not demonstrable.

Some work in Dr. Schnitzler's clinic at the Franz Josef Hospital, the results of which recently appeared in the *Wiener Klinische Wochenschrift*, has attracted a good deal of attention in Vienna, and as it seems to furnish an exact and reliable index of the beginning of suppurative processes, it may prove of special service in surgery. In the matter of appendicitis, an index of the beginning of suppuration, *i.e.*, of some definite reliable sign that the catarrhal process has become a suppurative one, has long been a desideratum. From the observations made, there is claimed to be present at the beginning of acute suppuration a characteristic iodine reaction in the blood. This is not attributable to the presence of the extracellular granules described by Ehrlich, and thought by him to be due to extracellular glycogen, but is an intracellular reaction. Ehrlich's iodine-gum solution is used, and the extracellular granules are found increased in suppurative processes, though the authors do not agree in attributing them to glycogen. Besides this, however, some of the polynuclear neutrophile leucocytes exhibit a characteristic yellowish-to-brownish color. This does not occur in the eosinophiles and only in certain polynuclear cells. It was observed but three times in over 1000 preparations in mononuclear cells.

This intracellular iodine reaction occurs only in acute suppuration and disappears twenty-four hours after an abscess has been evacuated. Where an inflammatory infiltrate does not become purulent, but goes on to resorption, it does not occur. Its appearance seems to coincide very closely with the occurrence of suppuration. The intensity of this iodine reaction is dependent upon the course and progress of the suppurative process. The more rapid the purulent degeneration and the more invasive it is, the more intense is the intracellular reaction to the iodine solution. Where a stationary abscess exists, *i.e.*, one where the purulent invasion of tissue is at an end, and nature has walled off the infecting material, the reaction does not occur unless for some reason the natural resistance is weakened and infective invasion once more begins. The subject is not an entirely new one experimentally, and besides Ehrlich, Czerny, and others have noted the phenomena in question, or very similar ones, though not with the definiteness of the present observers.

The status lymphaticus—the lymphatic diathesis I suppose we would call it in English if that term has not been already pre-empted for something quite different—is attracting a good deal of attention here from clinicians and pathologists. The subject was first brought into prominence by the observations of Professor Paltauf, the medico-legal specialist. He noted, in a number of cases of sudden deaths from slight causes in comparatively young people, that there was present a hypertrophy of the

lymphatic tissues," especially such as were connected with mucous membranes all over the body. The tonsils were hypertrophied, the lymph-follicles at the base of the tongue enlarged, abnormal adenoid tissues were present in the pharynx, and all along the intestine the lymph-follicles were increased in size and number. With this, there was a dilated heart not dependent on valvular lesions. In addition, there was often present a hyperplasia of the vascular system, a congenitally narrow aorta with small peripheral vessels.

It was noted in a number of cases of death during chloroform narcosis that these conditions were present. People so constituted seemed to stand slight, sudden shocks very badly. A plunge into cold water, for instance, was sometimes followed by fatal collapse. Unaccountable drowning accidents found their best explanation at *post-mortem* in the presence of this peculiar diathesis.

The condition was observed with extreme rarity in autopsies on the middle-aged or older persons. Vital resistance seemed to be so lowered that this diathesis is almost inconsistent with longevity. It was noted that many of the young patients who succumbed unaccountably to attacks of the infectious fevers which seemed comparatively light—influenza, for instance, of typhoid or of pneumonia, had this generalized lymphatic hypertrophy.

The clinicians took the matter up at this point, and the prognosis of the infectious fevers begins to be considered a doubtful matter where lymphatic hypertrophy on the visible mucous membranes is observed. When this is accompanied by small peripheral blood-vessels, the prognosis is very guarded. The recalcitrant and relapsing cases of chlorosis are often associated with this condition. In many of the cases there is evidently great delicacy of constitution; development has been slow and incomplete, the genitals may be hyperplastic, hair and other epidermic structures may be incompletely developed. In many cases, however, none of these developmental retardations or anomalies is present. In fact, the individual may be strong, well developed, normally built, and without any external sign of a pathologic diathesis. A case which came up for autopsy not long ago, after a sudden death in chloroform narcosis, occurred in a perfectly healthy-looking man of twenty-eight, 5 feet 8 inches in height, weighing 155 pounds, with no physical anomalies. There was nothing but the widespread lymphatic hypertrophy, the dilated heart, and perhaps some slight vascular hypoplasia to account for the death.

SUCCESSFUL LIGATION OF THE SUBCLAVIAN ARTERY—MUSICAL MITRAL MURMURS IN CONNECTION WITH AORTIC STENOSIS—THE VALUE OF EXPLORATORY LAPAROTOMY *per se* IN REAL AND SUPPOSED MALIGNANT DISEASE OF THE ABDOMINAL ORGANS—THE MORE EXTENDED USE OF ERGOT IN OBSTETRICS—A CLOT IN THE MITRAL ORIFICE PRODUCES SYMPTOMS OF STENOSIS—PARTURITION ACCOMPLISHED DURING PARAPLEGIA.

At a meeting of the Royal Medical and Chirurgical

Society, held May 26th, CLUTTON reported a case of *subclavian aneurism successfully treated by ligation*. The first part of the artery was twice ligated, the aneurism being in the third portion. A few days later a distal ligature was also applied to the first part of the axillary artery. The first ligature was one of gold-beater's skin. After six weeks the radial pulse had returned, presumably as a result of the absorption of the ligatures. The artery was then tied with floss silk. One week later the radial again was pulsating. The axillary artery then was tied, also with floss silk, which caused all pulsation in the aneurism itself to cease, and the dilated vessel gradually shrunk. Care was taken in applying the ligatures to the subclavian artery not to rupture the internal coat. If this takes place, there is danger that the vessel may give way or that a new aneurism may be formed at the site of the ligature.

Clutton also described a case of pharyngeal abscess followed by hemorrhage, and treated by ligation of the carotid arteries on one side. The trouble began with sore throat, followed by an abscess in the pharynx above the right tonsil, which extended into the tissues of the neck. There was considerable bleeding from the abscess cavity, which increased in spite of gauze packing. Accordingly, the bifurcation of the common carotid artery was exposed and the main trunk and both of its branches ligated. The patient made a rapid recovery. Experiments upon animals, as well as clinical data, show the necessity of ligation of both the internal and external carotids in such cases, and as the common carotid can be tied through the same incision, it does not complicate the operation.

At the meeting held June 8th, DICKINSON read a paper upon *musical mitral murmurs in connection with aortic stenosis*, based upon the examination of four cases. In one there was during life much evidence of intraventricular tension and an intense apical systolic murmur which had a musical tone. After death the aortic orifice was found to be almost completely closed, while the mitral valve was practically normal. The musical murmur was attributed to the overdistention of the ventricle, due to the obstruction of the aortic exit and the consequent leakage of the mitral valve under the abnormally high pressure.

In a second case, one of aortic disease of long standing, a murmur developed indicative of mitral regurgitation, with a squeak like that of a mouse. The left ventricle was found to be greatly hypertrophied, and both the mitral and aortic orifices were contracted and thickened. The other two cases were similar to this one. In every instance the musical murmur was attributed to the occurrence of mitral regurgitation in small volume and at a high pressure, the result of ventricular hypertrophy and obstruction.

At a meeting of the British Gynecological Society, held May 13th, SNOW read a paper upon *the value of exploratory laparotomy per se in real and supposed malignant disease of the abdominal organs*. The beneficial results which follow the opening of the abdominal cavity in tuberculosis are well known. In malignant troubles the resulting benefit has been overlooked through the

common practice of sending the patient home as incurable as soon as the wound has healed.

A woman, aged fifty-three, had a rapidly-advancing, very vascular deposit in the omentum, secondary to scirrhous of the breast. After incision the advance was materially checked, the mass diminished in size, there was no ascitic trouble, and the woman lived eighteen months. In a man aged fifty-eight years, with extensive deposit of carcinoma along the whole posterior surface and most of the greater curvature of the stomach, great improvement took place after incision, but the patient was soon lost from observation. An exploratory incision was made into a large sarcomatous mass, infiltrating both recti, of a man aged sixty-four. The growth diminished in size, and eleven months later there had been no bad symptoms, and the patient worked regularly as a sawyer.

ROBSON said that he had operated upon cases in which, upon opening the abdomen, he believed that he had to deal with ineradicable malignant disease, and had closed the abdomen without further procedure, yet the patient had quite recovered. Increased experience will, he thought, show that many of these conditions are not malignant.

On April 13th, MADDEN read a paper on *the larger use of ergot in obstetrics* before the Section on Obstetrics of the Royal Academy of Medicine in Ireland. By the teachings of some recent authorities, a trend of modern opinion has become established distinctly unfavorable to the general use of ergot during labor. The dangers ascribed to its use during labor are: (1) Its possible feticidal effects; (2) the probability of its giving rise to such irregular uterine action as will favor the retention of the placenta, and (3) the direct toxic effects of the drug upon the maternal organism. The first of these reasons has long since been disposed of by Denham and more recently by the experience of Atthill.

As to the second and third reasons, Madden quoted from his personal experience in 150 obstetric cases in which ergot was used. In 148 cases the maternal result was favorable. In 1 case the mother died from septicemia and in 1 from typhoid fever. In 95 cases the drug was given before the birth of the child. In 92 of these instances the children were delivered alive, either with or without forceps. Of the 3 who were still-born, 2 were found to be putrid, having been a long time dead. In 86 of these 95 cases the placenta was normally expelled. In the remaining 9 assistance was necessary four times on account of morbid adhesions, four times for uterine inertia, and once on account of hour-glass contraction.

Madden concludes that many of the evil effects ascribed to ergot are the result of its misuse. Under no circumstances should it be given during labor until the os uteri is fully dilated or fully dilatable. When given after delivery it checks hemorrhage, produces permanent contraction, and by sealing up the uterine vessels the liability to bacteriologic invasion is lessened. In the majority of multiparous patients it may be administered during the puerperal period with the object of stimulating the muscular tonicity and accelerating the process by which it returns to a normal condition.

EWART and ROLLESTON gave the details of *an autopsy at which the left side of the heart had been found to contain a large clot, plainly ante-mortem*, and which was attached to the left wall of the left auricle, and passed through the mitral valve into the ventricle. The valve was normal. The patient, a woman aged forty-three, after recovery from an attack thought to be pleuropneumonia, developed the symptoms of mitral stenosis, with failure of compensation. At first there was noticed a slight systolic murmur with a snappy first sound. Later a presystolic murmur developed. The thrombus was old internally, a recent clot having been added to it. The viscera showed the changes met with in cases of advanced mitral disease.

ROUTH, at a meeting of the Obstetrical Society, held June 2d, read a paper on *parturition during paraplegia*. A multipara with complete paraplegia below the level of the sixth dorsal vertebra, of traumatic origin, was admitted into the hospital half an hour after the accident. She was at the time nearly seven-months' pregnant. Two months later—that is 261 days after the last menstruation, labor came on without the patient feeling any pain. The first stage lasted ten hours, and the second $2\frac{1}{4}$ hours. The only sensation during a "pain" was a tight feeling at the epigastrium, inclining her to hold her breath. As the head was passing the vulva, the patient cried out—apparently a reflex act. Routh concludes that the act of parturition is partly automatic, partly reflex, and that direct communication between the uterus and the lumbar enlargement of the cord through the medium of the sympathetic nerve is probably essential to the regular and co-ordinate contraction and retraction of the uterus as occurring in normal labor. It also seems probable that the uterus is able automatically to expel its contents even when completely separated from the spinal cord, but such expulsion would be irregularly or imperfectly carried out.

At a meeting of the Epidemiological Society, held May 21st, DAVIDSON read a paper on the *seasonal fluctuations of epidemic diseases*, which recur constantly in every country, but vary in different climates and seasons. In seeking the causes of these variations, a distinction must be made between diseases like cholera, malaria, enteric fever, etc., which are due to the action of microbes existing in the soil, and diseases such as smallpox and measles, for the latter can be influenced only indirectly by meteorologic conditions, as these may affect the individual. Why epidemics occur usually in winter and spring, it is not easy to say. In Europe, India, and America, smallpox approximately follows the temperature curve, though it begins to rise in winter when the temperature falls, but attains its maximum during the spring. The regular appearance of smallpox during the winter has been ascribed by Fluegge to the aggregation of persons indoors, the less frequent change of clothing, and neglect of bathing; but this will not explain the occurrence of the same general curve in India, where the domestic habits do not conform to those of Europe. During 1868, smallpox was prevalent in Madagascar, with a temperature ranging between 90° and 100° F., while during the winter of 1870 in the Hudson Bay Territory an epidemic was not checked in the least by a daily temperature of 4° below zero. Weather

conditions which tend to produce catarrh of the pharyngeal and respiratory mucous membranes will, of course, increase the number of cases of measles, scarlet fever, and diphtheria by lessening the power of resistance of that part of the body by which the microbic cause of these diseases enters the organism. Similarly, catarrh of the intestine favors the development of cholera and typhoid fever.

RANSOME agreed with the reader as to the influence of catarrhal affections favoring infection, but he has also observed that seventy per cent. of the outbreaks of scarlet fever are preceded by a fall of the barometer, thus suggesting the sudden escape of the poison with the ascent of sewer- or infected ground-air.

Berlin.

PURPURA FULMINANS, OR ERYTHEMA EXUDATIVUM MULTIFORME—PASSAGE OF ESOPHAGEAL BOUGIES WITH THE AID OF THE ESOPHAGOSCOPE—A CASE OF HODGKIN'S DISEASE RESULTING FROM A BLOW ON THE SHOULDER.

At a session of the Medical Society, held May 12th, GEORGES presented a boy, aged two years, in whose case he had made a diagnosis of *purpura fulminans*. The child never had had any infectious disease, and, except for slight symptoms of rickets, appeared perfectly healthy until he was suddenly taken ill with obstipation, vomiting, and high fever. Some powders, probably of calomel, were administered, and a green diarrhea resulted. Eight days later the fever had disappeared and the boy was entirely well. Two weeks afterward the mother noticed a few red flecks on the buttocks. The next morning there was vomiting of blood, the appearance of a large blue-red spot on the calf, and a swelling of the opposite foot. On the following morning, the third day of the disease, there were several bloody dejections, and the ears, cheeks, hands, feet, and backs of both thighs and buttocks were swollen and the seat of numerous ecchymoses and bullæ, from the size of a pin-head to that of a silver mark piece. The scrotum was swollen and of a deep red color. The internal organs presented no lesions. Examination of the blood and urine showed nothing abnormal. There was elevation of temperature up to 103.5° F.

The case was remarkable on account of the rapidity with which the hemorrhages occurred. The treatment consisted of rest in bed, a proper diet, and the administration of iodid of potash.

LASSAR looked upon the case as one of acute erythema febrile bullosum rheumaticum, the disturbance of the digestive tract and the pains with which such cases are often affected pointing to the relation to gastrorheumatic troubles. Under these circumstances he gives as large doses of salicylate of soda as the age and condition of the patient will warrant.

HEUBNER said that all the cases for which Henoch had proposed the name purpura fulminans had ended fatally. Such a case, however, he never had had the good fortune to see. Further, the occurrence of bullæ was not in accord with the classic picture of that affection. The diagnosis of erythema exudativum multiforme was, in his opinion, the correct one.

JACUSIEL reported the following interesting and un-

usual case: A young man, aged twenty, was struck on the shoulder by a board. Soon after there developed at the site of the injury a tumor, which grew for four years without symptoms. Then in the neighborhood of the tumor, in the neck and around the scapula, there were found a number of enlarged glands. The case progressed unfavorably in spite of a long-continued treatment with arsenic, the liver and spleen became much enlarged, ascites set in, and death followed—eight years after the injury was received. A complete autopsy was not permitted, but examination of the tumors showed them to have no characteristic structure, giant cells being found only in two preparations. A probable diagnosis of Hodgkin's disease was made, which, it was admitted, was only a cloak for inability to arrive at a proper solution of the malady.

VIRCHOW, who had examined the tumors microscopically, said that an exact diagnosis was impossible, but that the glands presented the appearance of malignant glandular sarcoma (lymphosarcoma), or, as commonly called, Hodgkin's disease.

ROSENHEIM has been able to pass a sound with the aid of the esophagoscope in the case of two patients suffering from stricture of the esophagus, although without this instrument he repeatedly failed in the attempt. In both patients the stricture was at a distance of twenty-eight centimeters (eleven inches) from the teeth. The cause of constriction in one instance was a carcinoma, and in the other it was the scar following the swallowing of a strong alkali. In the first-named case relief was naturally only temporary; in the latter an opening which at first would admit only the finest probe, and which was found only with the greatest difficulty even with the esophagoscope, was so far dilated by treatment as to permit the patient to swallow food of the consistency of oatmeal without difficulty, while a seven-millimeter bougie could be easily passed.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held Wednesday, April 21, 1897.

L. DUNCAN BULKLEY, M.D., President *pro tem.*, in the Chair.

DR. S. H. DESSAU reported a case of diphtheria in which brilliant results were obtained by the use of antitoxin. The patient was a child between two and a half and three years old who was brought to the West Side Dispensary. There was very difficult, harsh breathing of a croupy character, and the case was diagnosticated as laryngitis by his assistant. The speaker saw the child a day later, and examination revealed the fact that the tonsils and a portion of the soft palate and lower posterior pharynx were covered with a grayish exudate. It was decided to employ antitoxin, although the prognosis was exceedingly bad. The Board of Health preparation was given, five cubic centimeters, representing 2500 units, being injected. The child immediately began to improve and is now convalescent.

DR. J. RIDDLE GOFFE spoke of the value of combined operations in saving time and nervous wear and tear to the patient, and reported the history of a case in which he first curetted the uterus and packed it, and then shortened the round ligaments by the following new method: An incision was made in the anterior vaginal fornix through which the uterus was delivered, and the round ligaments were then caught up and shortened by being folded upon themselves and stitched together. The uterus was then replaced and an operation for repair of the lacerated perineum performed, after which the patient was turned upon the left side, an incision made through which a floating kidney was found, brought up, and stitched in the wound. The patient rallied well, although she was pale, anemic, and in a wretched condition before the operation. The entire procedure lasted an hour and three-quarters, and the anesthetic used was chloroform, about three ounces being given.

DR. R. A. MURRAY believed the principle a correct one, and thought it advisable to combine such operations whenever one did not preclude another, as, for instance, an operation for repair of the perineum when drainage *per vaginam* is to be employed, in which case good union of the perineum cannot be obtained.

DR. WILLIAM STEVENS said he had recently had the misfortune to see a man die from the effects of chloroform. About half an ounce of the anesthetic had been administered, when the man threw back his head and expired in less than five minutes, although half a dozen doctors tried to resuscitate him. The man had been somewhat intemperate in the use of alcohol, and possibly there was some carelessness in administering the chloroform.

DR. A. M. JACOBUS thought the danger in chloroform anesthesia lies in the fact that too much of it is given in the beginning. Instead of commencing with a few drops, as much as half a teaspoonful is often poured on the mask. In the case mentioned death was probably due to sudden paralysis of the heart.

Dr. Jacobus then reported a case of belladonna poisoning caused by wearing a belladonna plaster. The patient was a woman for whom he had prescribed fluid extract of hydrastis for metrorrhagia at the Presbyterian Hospital Dispensary, the drug being put up for her at the dispensary drug department. After taking two or three doses of it she began to feel and act queerly. She therefore took the bottle to a drug-store, where the clerk told her it contained laudanum. She immediately hurried to the speaker's office in a terrible state of excitement. Her face was flushed, the pupils widely dilated, the throat dry, she complained of numbness, and was dazed and unable to talk connectedly. The symptoms all pointed to belladonna poisoning, but no connected history could be obtained. The medicine, which she had with her, was found to be fluid extract of hydrastis, and the speaker was at a loss to account for the symptoms until, upon stripping her, he discovered that she was wearing a belladonna plaster. She began to improve when this was removed, and was soon entirely well.

DR. S. H. DESSAU said that hydrastis might easily be

mistaken for laudanum, as the odor is quite similar, but thought such an error on the part of the drug-clerk was unpardonable. The yellow staining of the fingers by hydrastis at once makes clear the difference, and, moreover, its physiologic effects are entirely unlike those of opium. The symptoms complained of by the woman were more like those following a very large dose of quinin.

DR. MURRAY said he was very careful in prescribing belladonna, and always told the patient the nature of the drug, for he had seen several cases of poisoning from its use. He expressed the opinion that some people, especially children, show an idiosyncrasy in regard to belladonna.

DR. JOSEPH COLLINS said it seemed to him that children are very tolerant of belladonna, and that he has often given a dose to a child which would produce unpleasant symptoms in an adult.

DR. J. H. FRUITNIGHT reported an interesting case in which there was loss of motion and sensation in both extremities. The patient was a woman, sixty years of age, who had always been perfectly well up to the time of the attack. On attempting to rise one morning she found that there was a total loss of motion and sensation in the lower extremities. There were no symptoms referable to the central nervous system, and no cause could be found for the paraplegia except the fact that she had not passed much urine. Upon passing the catheter, only a small amount of urine was found in the bladder. Diaphoretics were administered, and a considerable quantity of urine was voided, which was found to contain granular, epithelial, and hyalin casts, albumin, and some pus-cells. Improvement soon followed, and the patient is now able to walk about. With such a result, the speaker thought it seemed improbable that there was any cerebral lesion, and considered the paraplegia due to uremic poisoning caused by suppression of urine.

DR. COLLINS thought the case neither strictly organic nor functional. The lesion was probably a spasm of the blood-vessels in the cord which prevented transference from both above and below, such a condition being quite possible. He doubted whether there was complete sensory paralysis, for, as he understood it, the patient had first tested herself in this regard. Unless both tactile and pain sensation were tested, he thought the case one of motor paraplegia due to uremic poisoning.

DR. COLLINS reported two cases which he had recently seen with Dr. Brewer. The first was that of a man who had an ordinary suppurative cellulitis of the posterolateral portion of the neck which was incised. The patient was apparently doing well when he began to develop symptoms of what was supposed to be cerebral abscess. There was a temperature of 102° F., the pulse was rapid, and the mental condition was impaired. There was no stiffness of the neck and no reflexes. The man died shortly afterward, and at the autopsy an extensive cerebrosplinal meningitis was discovered.

The second case was that of an old woman, from whom a tumor of the breast has been removed. The wound remained open and was filled with large granulations, and

there was a condition of general sepsis present. She developed stiffness of the face and one side of the tongue, then of one side of the body and then of the other, and a slight arching of the back. There were no symptoms of hysteria. The case was at first supposed to be one of meningitis, but it was noticed that the stiffness disappeared under manipulation, and it seemed probable that it was a toxic manifestation. She was given calomel and Carlsbad salts and a cold douche, with the result that she recovered.

TYPES OF INFLUENZA IN 1896-97

was the subject for the evening's discussion.

DR. ROBERT MILBANK said that he had seen many cases of gripe during the past winter, but had met with fewer cases of pneumonia and serious affection of the respiratory organs than ever before. The cases which struck him most forcibly were those which were accompanied or followed by intercostal rheumatism. He had seen a number of cases complicated by throat trouble, such as suppurative tonsillitis.

DR. RICHARD KALISH said that his experience with gripe was limited to those cases in which there was some eye or ear complication. He had seen few cases in which there was any ear involvement, but had treated many for catarrhal conjunctivitis which developed during convalescence and was usually of short duration.

DR. J. BLAKE WHITE said that whereas some years back the respiratory organs seemed to be the ones most affected by gripe, his experience during the past year went to show that the digestive organs suffered most. He had seen few cases of pneumonia, but quite a number in which there were throat complications. He had found bromoladin especially useful in relieving the irritation of the throat in these cases. Opiates he had found not so useful as subnitrate or subgallate of bismuth, together with resorcin; he prefers carbonate of ammonia with salicylate of soda.

DR. DESSAU spoke of the disease in children and thought the type had changed during the last few years. Formerly there were many violent symptoms, such as high fever, delirium, convulsions, and semi-coma, accompanied by pneumonia, pleurisy, etc., while of late the symptoms have been of a much milder type, and in many cases have been attributed to catarrh or some form of digestive disturbance, until the persistence of the attack excited suspicion, and the successful results following a specific form of treatment revealed the true nature of the disease. The principal feature of the mild form of influenza in young children is a teasing cough, worse at night, occurring in paroxysms at times, with but little expectoration, accompanied by a few râles of the dry, subcrepitant variety. In the majority of the cases observed by the speaker there was no marked involvement of the nasopharynx, although there was a mild pharyngitis. In this connection he referred to concealed forms of diphtheria located in the nasopharynx. A differential diagnosis can be made by rhinoscopic examination and from the appearance of the secretion. In diphtheria it is thin, viscid, and seems to run down the posterior wall in a stream; in influenza the discharge is almost green in color and quite

thick, showing itself below the soft palate in lumps. In treating influenza he has used with great success a one-per-cent. solution of carbolic acid, with a little glycerin added.

DR. FRUITNIGHT was of the opinion that the type of the disease had been less severe during the past year, and that it would continue to diminish in the course of time, and would eventually disappear. He had seen but little pneumonia, the most common complications being nose, throat, and middle ear diseases, which, however, yielded rapidly to treatment. He had seen little of the neurotic form of the disease which was so common in the first epidemic, but had been struck by the frequent occurrence of neuralgia, especially of the frontal sinuses, in these cases. In his experience children had not been so generally affected as old people.

DR. MURRAY said that in every case he had seen the frontal headache was an important feature. Nose, throat, and ear complications were also common. He is in the habit of giving the patient calomel, and then prescribes phenacetin and codein to relieve the headache. The intense prostration which follows the disease demands tonics.

DR. A. E. BIESER, present by invitation, said that, clinically, the disease appeared in four types, affecting respectively the respiratory, the circulatory, the nervous, and the gastro-intestinal systems. Of late years the disease has been of a milder character than that which was seen in 1891, and the cardiac failure, which was then so common, is now rarely seen. He expressed the opinion that much of the heart failure in gripe is due to the use of coal-tar preparations, and said that at one time when the supply of phenacetin had given out many druggists substituted acetanilid. He, therefore, did not employ the coal-tar preparations in the treatment of influenza, but replied upon whisky, quinin, and tonics. If it were necessary to treat individually the symptom *pain*, he would prescribe opium.

DR. JOHN F. ERDMANN presented a specimen of ruptured tubal pregnancy taken from a patient from whom, fourteen months before, he had removed the opposite tube for a similar condition. The woman, who was twenty-six years of age, was in collapse when first seen, with symptoms of concealed hemorrhage, pulse 144 to 148, respirations rapid and shallow, rupture evidently having occurred some days before. The abdomen was opened and the ruptured tube removed. During the operation six pints of normal salt solution were injected. The patient was making a good recovery.

DR. ERDMANN also exhibited a specimen showing sarcoma of the testicle, which was removed from a man thirty-five years of age in whom there was no family history of malignant disease, and no specific history. Some years ago he had a hernia. When first seen a tumor of the left testicle, about the size of an egg, was found. It was not translucent. Two weeks later the tumor had greatly increased in size, some fluctuation was noticed, and the case was thought to be one of hydrocele, although the rapid growth pointed to sarcoma of the testicle. Operation was advised and the growth removed. A

hydrocele containing about four ounces of fluid was found in the lower part of the tumor, which was evidently sarcomatous, although no microscopic examination had as yet been made.

NEW YORK ACADEMY OF MEDICINE—SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, Held May 21, 1897.

A. B. JUDSON, M.D., in the Chair.

DISLOCATION OF THE PERONEUS LONGUS AND PERONEUS BREVIS.

DR. W. R. TOWNSEND presented a young man, twenty years of age, whose peroneal tendons were easily dislocated to the front of the malleolus. The right foot had been affected in this way for many years, the left only during the past seven months. On walking and on rising from a chair the tendons would slip over the malleolus and cause considerable disability until they were replaced by the hand. The boy did not have much pain, but was easily fatigued. Dr. Townsend briefly reviewed the literature of the subject. Dr. L. A. Sayre reported a case in 1870. In 1876, Dr. Beach of Boston reported eighteen cases, including one of his own. Gillet de Grandcourt reported ten cases in 1878. Treves said it is caused by sudden and violent contraction of the muscles when the limb is in such a position as to favor displacement, that it may be treated by means of pads and pressure, and that in some cases it is advisable to replace the tendons and retain them by suturing the torn edges of the sheath.

DR. R. WHITMAN suggested deepening the channel, replacing the tendons in the groove in the bone and giving them a new covering of periosteum or fibrous tissue. This might be possible without removing the sheath.

DR. A. B. JUDSON said that the peronei are comparatively small and unimportant muscles. To a slight degree they assist the muscles of the calf to extend the foot on the leg. Aside from this their function is to evert the sole of the foot, and this function is not seriously impaired by displacement of the tendons to the front of the malleolus. He thought that the patient would derive no benefit from an operation, and that practically no treatment was necessary.

DR. WHITMAN said that the discomfort caused by the slipping of the tendons must be considerable, and that the boy would be better off if this could be stopped.

DR. TOWNSEND said that the patient had recognized the disability and had sought advice on account of it. He thought an attempt should be made to prevent the slipping of the tendons by the application of pads and pressure before an operation was decided upon.

A CASE OF TRAUMATIC SPINE, WITH RECTAL AND VESICAL PARALYSIS.

DR. J. P. FISKE presented a patient, a man thirty-three years of age, who had been under treatment during fourteen months, and under observation thirty-four months, from the time of the injury. When first seen he was in a condition of complete helplessness. He could not move in bed, and if turned or moved by his attend-

ants he suffered the greatest pain. Urine was constantly flowing, and he was not conscious of the passage of feces. Recovery had been complete, with control of the sphincters. He was now walking without assistance and had returned to his work. The accident had been attended by great violence. While working as a harness-maker the flooring gave way under him as he was carrying a heavy load and his right leg went through a hole. The spine was forcibly flexed and he became unconscious. The twentieth day after the injury, rigidity of the spine and muscular spasm were marked. There were complete paralysis from the waist down, as regards voluntary motion, incontinence of urine and feces, and pain in the dorsolumbar region, aggravated by the slightest motion. Crepitus and spinal deformity were absent. The diagnosis was severe traumatism of the spine, concussion of the cord, more or less complete rupture of the ligaments, and, possibly, partial dislocation of one of the lumbar vertebræ, with spontaneous reduction. He was at once encased in plaster-of-Paris from the axillæ down to and including the pelvis, with immediate and considerable relief.

The plaster jacket was renewed when necessary and was worn day and night during ten months. This treatment, with massage, frequent change of position, alcohol baths, and such medication as was required in his poor general condition and for the vesical symptoms, was attended by gradual recovery. There were no bedsores. At the end of four months he sat up in bed and was lifted into a steamer-chair. After seven months he had regained control of his rectum and could walk a short distance with the aid of crutches. From this time his recovery was more rapid. The incontinence of urine persisted longer than the other symptoms, but ceased after a time, and during the past twelve months he had been perfectly well. This case clearly shows the immediate and permanent relief which follows absolute fixation after severe spinal injury. Patients treated without persistent fixation are likely to be constantly troubled with pain in the back and legs, and to present the symptoms of railway spine. Dr. Fiske added that these cases are often considered hopeless. He had presented the patient as an example of what continued fixation and supporting treatment would accomplish.

AN ISCHIATIC CRUTCH USED IN PLACE OF AN ARTIFICIAL LIMB.

DR. A. B. JUDSON presented a boy nine years of age, who was wearing an ischiatic crutch instead of axillary crutches or an artificial limb. Amputation had been performed below the knee after a railroad accident. The case illustrated the comfort and ability which this apparatus was able to secure in the treatment of those affections of the lower extremity which require that the weight of the body be removed from the affected limb. This use of the skeleton of the pelvis is not new. Ischiatic support is a feature of Dr. Fayette Taylor's hip-splint, described in 1867. In fact, the long hip-splint is an ischiatic crutch with the added function of traction. In the instrument shown the crutch consisted of an upright steel piece,

adjustable in length to meet the growth of the patient, with an india-rubber crutch tip at the foot and a semi-circular pelvic band, carrying a single perineal strap. It also had a shoulder strap which transferred the weight of the splint to the opposite shoulder, a steel knee-piece restraining the limb anteroposteriorly, and a webbing strap above the knee. There was no customary leather strap surrounding the splint and the ankle because the lower part of the leg was absent. Although the stump was flexed in walking, there was no possibility of ankylosis interfering with the subsequent use of an artificial leg, because the knee was free from inflammation, which necessarily preceded ankylosis. The apparatus was easily provided with a joint at the level of the knee, and this is desirable in convalescent hip disease, if the limb is so long as to be inconvenient if constantly extended.

OSTEOTOMY FOR INVERSION IN CLUB-FOOT.

DR. TOWNSEND, at the request of Dr. V. P. Gibney, presented a girl, five years of age, whose feet had been treated by Phelps' operation, by braces, and by building up the outer side of her shoes. On February 16, 1897, to correct inversion, subcutaneous osteotomy of both tibiæ had been performed, and also right achillotomy. The lower fragments of the tibia were rotated outward and the limbs put in plaster-of-Paris. The inversion had been entirely corrected. Mr. R. L. Swan of Dublin, who had described this operation, after an experience in the treatment of twenty patients with good results, had said that rotation of the limb as the result of equinovarus, and which persists after the latter is corrected, is due to trouble below the knee; that when these patients walk and attempt to toe out they throw the entire limb out by rotation of the thigh, and the gait is awkward. The toeing in is due to the fact that the entire leg is rotated inward and the external malleolus is too far forward. To overcome this, he divides the tibiæ only, rotating and bringing the lower fragment outward, thus placing the internal malleolus further forward, as regards its relation with the external malleolus.

DR. JUDSON said that, for the prevention of inversion, he relied on the thorough correction of the equinovarus. If this is done, the child avoids toeing in, either unconsciously, or, later, from pride.

DR. WHITMAN said that division of the bones of the leg is a very old operation for the correction of the intoeing of club-foot.

DR. TOWNSEND said that Mr. Swan divides only the tibia and is very careful not to divide the fibula.

DR. TAYLOR had noticed that the feet in the case shown had not been fully corrected before the operation. The child walked very well now and the result was very good, but it seemed uncertain that this condition would prove permanent. He believed that the persistence of inversion in many of these patients is due to incomplete correction of the deformity.

CALCANEVALGUS, WITH SUBLUXATION OF THE ASTRAGALUS.

DR. TAYLOR presented a baby affected with congenital calcaneovalgus, with a very unusual degree of dislocation

or subluxation forward of the astragalus. The heel was unduly prominent. The astragalus was displaced forward, while the fibula was behind its normal position. Treatment had consisted of gradual reduction and plaster-of-Paris fixation.

COXA VARA.

DR. WHITMAN presented a boy, sixteen years of age, affected with a bending of the neck of the femur, which condition had existed about twelve months. He walked with a limp and eversion of the foot. The elevation and prominence of the trochanter was increased by flexion. Limitation of abduction, actual shortening of one-half inch, with marked apparent shortening from habitual adduction, all were present. The treatment would be to remove the weight of the body from the weak femur by the use of a perineal crutch, massage, forcible stretching of the adductors and, if necessary, subtrochanteric osteotomy. Bending of the neck of the femur is not due to general rickets or the rickets of adolescence, of which there are cases on record. There is, however, a weakness of adolescence which, under favorable conditions, causes this and similar deformities.

REVIEWS.

HYPNOTISM AND ITS APPLICATION TO PRACTICAL MEDICINE. By OTTO GEORGE WETTERSTRAND, M.D., of Stockholm. Authorized Translation by HENRIK G. PETERSEN, M.D., together with Medical Letters on Hypnosuggestion, etc., by HENRIK G. PETERSEN, M.D. New York: G. P. Putnam's Sons, 1897.

MUCH has been written on hypnotism and suggestion, and much of it is of but little value. To the present book this characterization cannot apply, for the author, while an enthusiast, is not fanatically devoted to this agent as a panacea for all earthly ills. The work is more practical than theoretic, and embodies the results of critical powers of observation. It gives an account of the various ailments to the relief of which the author has applied this therapeutic measure and presents the cases, 128 in number, in which the results have justified the means.

The author's conclusions are modest. He regards functional nervous diseases as most adapted to treatment by suggestive therapeutics. He distinctly says: "I do not see a panacea in hypnosuggestion, to the exclusion of all other means and methods, nor do I in the least wish to assert that its use is always successful." Everyone interested in psychotherapy will find some points of interest in the book.

DIPHTHERIA AND ANTITOXIN. By NESTOR TIRARD, M.D. London: Longmans, Green & Co., 1897.

THIS book deals with the author's personal experience in the treatment of diphtheria. He is a devoted advocate of the use of antitoxin, a position justly based on the record of his cases.

The book presents nothing new, its merit being in the felicitous manner of the presentation of the subject.

NEW YORK, SATURDAY, AUGUST 14, 1897.

No. 7.

ORIGINAL ARTICLES.

ON THE OCCURRENCE OF PRIMARY TUBERCULOSIS OF THE KIDNEY, WITH SPECIAL REFERENCE TO A PRIMARY MILIARY FORM.¹

By DAVID D. STEWART, M.D.,
OF PHILADELPHIA;

PROFESSOR OF DISEASES OF THE STOMACH AND INTESTINES IN
THE PHILADELPHIA POLYCLINIC; VISITING PHYSICIAN TO
THE EPISCOPAL HOSPITAL, ETC.;

AND

ALOYSIUS O. J. KELLY, M.D.,
OF PHILADELPHIA;

ADJUNCT PROFESSOR OF PATHOLOGY IN THE PHILADELPHIA
POLYCLINIC; VISITING PHYSICIAN TO ST. MARY'S
AND ST. AGNES' HOSPITALS.

At the inception of a study of the subject of tuberculosis of the kidney we appreciate the fact that under the same generic term are grouped certain diverse, morbid conditions having nothing in common but their mutual dependence upon the same morbid agent—the tubercle bacillus of Koch. The varying manifestations of tuberculosis of the kidney differ not only as to the time of their occurrence with respect to other possible tuberculous lesions in the body, but also as to their pathologic anatomy, their symptomatology, their diagnosis, their prognosis, and their therapeutic indications. The implication of the kidney in the tuberculous process has interested numerous investigators for a very long time, but their observations usually have been limited to those cases in which the renal involvement was secondary to some other well-established tuberculous lesion in the body. It is but recently—within the past half century—that the possibility and the fact of the occurrence of primary renal tuberculosis has received more than cursory attention; and it is the outcome of these recent studies which has resulted in the establishment of the fact that many cases of renal tuberculosis of supposedly secondary involvement are in reality instances of primary infection. Because of this fact, and reasoning from analogy, one is led to the not unwarranted supposition that primary renal tuberculosis is much more common than is usually assumed.

As is well-known, tuberculosis of the kidney manifests itself in either of two general and quite distinct forms—either as miliary tuberculosis or as caseous

tuberculosis—the latter a condition variously described as chronic tuberculosis, chronic localized tuberculosis, renal or nephrophthisis, tuberculous pyelitis, or tuberculous pyelonephritis—the strumous or scrofulous kidney of the older writers. It is now generally admitted that the latter—that is, caseous tuberculosis of the kidney—may be a primary or a secondary affection; whereas the former—miliary tuberculosis—is commonly regarded as always being the result of secondary infection.

Miliary tuberculosis of the kidney is an acute process, and is generally believed to affect both kidneys. It occurs secondarily to tuberculosis of any of the bodily organs, especially of the lungs, glands, or meninges; and less commonly of the bones, joints, bladder, prostate, etc. It occurs in association with the general dissemination of miliary tubercles throughout the body—in the liver, spleen, lungs, serous membranes, etc. Infection usually takes place by means of the blood-vessels, though if the primary focus be in the lower urinary tract it is not impossible that infection may take place *via* the lymphatics, under which circumstances a unilateral involvement might ensue. The implication of both kidneys, however, is the rule, and there exists a tendency to the simultaneous involvement of more or less of the entire genito-urinary tract. The condition is quite common in the young, and is characterized by the development of varying numbers of small, whitish semi-translucent spots, which later develop into grayish-white or yellowish tubercles, which are generally surrounded by a zone of deeply congested renal tissue. As the infection in these instances is hematogenic, the tubercles are usually found to be most numerous in the cortex, where the bacilli become arrested in the terminals of the renal artery. But they vary much in number, and are not uncommonly distributed without any evidence of regularity. Sometimes they are arranged, as it were, in rows, in the direction of the *vasa interlobularia*, and instances have been recorded in which they seem to be confined to the region supplied by one branch of the renal artery. They usually remain isolated, evincing but little tendency to coalesce, nor do they show the marked tendency to degenerate so characteristic of the caseous form. Rarely, larger areas are formed by the coalescence of several smaller ones. Through tuberculous implication of the walls of the arteries, thrombi sometimes are formed, giving rise to anemic

¹ Read at the Twelfth Annual Meeting of the Association of American Physicians, held at Washington, D. C., May 4, 5, and 6, 1897.

or hemorrhagic infarcts; and at times the arrangement of the miliary tubercles in rows in association with the fatty degeneration of the neighboring renal parenchyma also presents an appearance not unlike infarcts, but the discovery of the small tubercles prevents the error. Microscopically, the tubercles are frequently noted in the Malpighian corpuscles, in which and in the adjoining uriniferous tubules the tubercle bacilli may be detected. The tubercles consist at first of small, roundish areas of epithelioid cells and round-cell infiltration, in the beginning, at least, quite well circumscribed. Later, giant-cells make their appearance, the epithelium of the uriniferous tubules participates in the process, undergoing fatty degeneration, and finally breaking down into a fatty detritus, upon which the entire area may exhibit more or less marked degenerative changes.

As this variety of tuberculosis of the kidney gives rise to few or no manifest disturbances of function of the kidney or of the urinary bladder, and as it is part of a general process of miliary tuberculosis which of itself gives rise to much more obtrusive symptoms than could the kidney lesion, the kidney involvement possesses but little clinical interest or importance. It can hardly be diagnosticated, although Rosenstein is said to have observed anuria in children under such circumstances. The condition, however, usually is not suspected prior to the *post-mortem*. Further, were it possible of detection, there would be no utility therein, as it is not amenable to any kind of treatment.

In contradistinction to this the usual form of miliary tuberculosis of the kidney—a secondary affair—there is another class of cases in which miliary tuberculosis of the kidney occurs as a primary affection and involves but one kidney. These cases must be of some rarity, as they usually are not referred to. Knowsley Thornton and Newmann make mention of the possibility of their occurrence, and Rosenstein and others suggest that the ordinary caseous variety may in its beginning present itself in the miliary form. But primary unilateral miliary tuberculosis of the kidney has, nevertheless, received scant notice. The usual implication of the kidney in the tuberculous process presupposes a tuberculous implantation in a kidney previously healthy. True, some few instances of mixed infection have been hinted at, and other cases of calculous pyelitis, for example, associated with tuberculous disease of the kidney, have been reported. But the occurrence of a primary circumscribed unilateral miliary tuberculosis of the kidney, and in a patient the subject of chronic nephritis, is considered sufficiently unique to justify the report of the following case observed in private practice:

J. H. K., female, aged forty-five years, married, consulted Dr. Stewart during October, 1894, for presumed cardiac trouble. One year previously she had suffered from a mild attack of articular rheumatism, which is said by her attending physician to have affected her heart. This, it had been presumed, accounted for the extreme and distressing breathlessness and palpitation of which she complained. It was stated that her health had always been fair until lately. The attack of rheumatism was said to have been slight. She had suffered considerably from headache during the past year and lately from attacks of severe dyspnea. The latter were becoming more frequent and pronounced, and amounted at times to the most distressing orthopnea. Dyspnea did not seem to be induced by exertion, and was most common during the night. Cough was absent save at the time of some of these attacks.

The patient was of spare build, of medium height, of brunette type, of nervous temperament, and weighed 115 pounds. Anemia apparently was so slight that a blood-examination was omitted. Physical examination of the heart showed the impulse to be extended. A murmur was audible, somewhat harsh, whistling in character, and systolic in time. Although readily discernible at the apex, its seat of greatest intensity was in the tricuspid area. Transmission to the left, other than to a very limited extent, did not occur. The murmur was inaudible beyond the apex. There was marked accentuation of the second sound of the heart; at the base it was more distinct to the right than to the left. Very high blood-pressure was apparent and persisted even after resort to very active purgation and the free use of arterial sedatives. The arteries were tense and of fair volume. The radial pulsation was not readily extinguished by pressure.

The lungs gave no indication of primary disease. Signs of passive congestion, posteriorly, chiefly at the right base, were common.

The abdominal viscera presented no indications of abnormalities.

An examination of the urine, made a few days after the patient was seen for the first time, showed a rather heavy sediment, which was found to consist chiefly of pus. There were present also a few epithelial casts, a number of fine and coarse granular casts, and hyalin cylinders and cylindroids.

The presence in the urine of pus in some amount, which repeated examinations showed to be usual despite any obvious bladder or vaginal condition to occasion it, naturally suggested the thought of tuberculosis of the urinary passages complicating a very obvious chronic nephritis. The patient was totally free from leucorrhea. It is of interest also to relate that although she had been married some twenty years, and was living happily with her husband, who was devoted to her, she was still a *virgo intacta*. The hymen was found later to be perfectly preserved; sexual connection, it was related, never had occurred.

The first search made for tubercle bacilli disclosed them in large number, presenting themselves commonly in typical clumps. Subsequently, these were

repeatedly found both by Dr. Stewart and by his assistant in laboratory work, Dr. Pottberg. Differentiation from the smegma bacillus, of course, was carefully made. When the patient first came under observation, the urine was apt to be turbid when voided, of low acidity, and readily decomposable. Subsequently, perfectly clear specimens were passed, depositing pus as formerly. A number of examinations of the mixed urine showed that albumin was present, commonly in about one-tenth per cent. by weight. An account of the daily twenty-four-hour urine was taken for two or three days weekly during the greater part of the time the case was under observation, both to maintain a watch on nitrogenous excretion and to determine as to a possible pyonephrosis. There were at no time indications of blocking of the ureter. The amount voided was commonly between 750 and 900 c.cm. It was readily increased by diuretics. The specific gravity usually was moderately low, as was the urea output. The latter, for her weight, should have been 25 grams; while even under full diet and diuretics it did not exceed 14 grams, and commonly was less.

The case was early diagnosticated as one of chronic nephritis, complicated by a probable tuberculosis of the kidney. There were no indications of involvement of the bladder. Vesical irritability, pain, and tenderness were altogether absent.

Although nothing was to be hoped for from a more exact knowledge, the patient acquiescing, Dr. C. P. Noble's cooperation was obtained to make an inspection of the bladder and to attempt to catheterize the ureters, in order to determine the extent of the tuberculous involvement. On cystoscopic examination, the bladder was found healthy. Catheterization of the ureters was attended with such difficulty, because of the very tight hymen, that the attempt was, for this reason, abandoned; and especially because, even if the tuberculous process had been found limited to one kidney, an operative procedure was out of the question.

The patient was under almost daily observation from the time she was first seen (October 21, 1894) until the date of her death—about five months later. During this time her symptoms were such as the chronic nephritis and an imperfectly compensated mitral valve lesion would occasion. There were pronounced uremic symptoms, which were held in check for several months by appropriate remedies, but during the two months preceding her death were totally uncontrollable. Early in February, 1895, she began to fail visibly. She was unable to leave her house. There was pronounced and persistent insomnia and debility. Dyspnea was the most obtrusive symptom; it occurred in spells, most frequently at night, which amounted to veritable attacks of orthopnea. Without apparent cause the respiration would suddenly become accelerated, reaching 50 or 60 per minute, and occasionally higher. This would persist for an hour or more. The attack would then subside, and a condition of comparative comfort ensue. With these attacks of dyspnea there was often pronounced pulmonary conges-

tion. In one of these spells, ten days before death, the indications were of the occurrence of pulmonary infarction. The patient was suddenly seized, while at rest, with difficult breathing; the respiration quickly ran up to about 70; the face became deathly pale and the extremities cold; there developed a short, hacking cough, with frothy, blood-streaked expectoration. The heart's action was tumultuous. Ammonium carbonate and whisky were administered by the mouth at frequent intervals, and strychnin given hypodermically, while oxygen inhalations were maintained and hot poultices applied to the chest. In the course of an hour the attack entirely subsided and the patient fell asleep. Two hours later, when again seen, she was resting comfortably; respirations were 30; the pulse 100; temperature, 100° F. The heart was overacting, with marked reduplication of the second sound. An area of solidification at the root of the right lung was apparent.

Free dry cupping in the early evening usually tended to prevent the occurrence of the night seizures, and a prompt resort to the same, on the appearance of the dyspnea, commonly afforded great relief. Oxygen inhalations were steadily used, and always with marked benefit.

Without cardiac medicaments of any sort, the heart generally overacted very much, with sharp accentuation of the second sound at the apex. High blood-pressure was so usual, even with symptoms which might have been presumed to be caused by imperfect compensation, that these last, such as decided dyspnea, could not but be regarded as uremic in character. Free purgation by calomel always relieved, if it did not entirely prevent, the attacks of dyspnea until toward the end.

Careful daily thermometric observations were made for two months prior to the death of the patient. Previously the temperature had often been taken when she was visited during the afternoon or evening. There was then commonly present slight elevation, not amounting usually to over 1½° F. During the two months preceding death the temperature did not exceed 100° F. It was generally 99° about noon, and from 99½° to 100° F. between 4 and 6 P.M.

Two months prior to death the stomach became much distended. Vomiting occurred at least once daily. The vomited matter contained no free hydrochloric acid. When food was present in the stomach, the vomit consisted of clear fluid, which a few days before death had a urinous odor. During the last two weeks of life, vomiting was quite incessant, whether food was taken or not. It was not readily controlled by drugs. It was clearly a uremic sign. The urine during the last month steadily diminished in quantity, not exceeding a daily amount of 600 c.c. Toward the end it fell to 150 c.c., totally without signs of retention in the kidneys. Casts were always found, and in the examinations, made a week or so prior to death, erythrocytes were present in some amount in addition to the pus-cells. High blood-pressure was maintained up to a day or so before death. The heart showed no signs of failure, being perfectly regular in action an hour

or so before dissolution. It continued overacting, with accentuation of the second sound at the apex. The systolic murmur could be heard only inconstantly during the last two weeks of life. For several days before death she vomited continually, and was stuporous. During the last two days she was comatose; the respirations were irregular, and generally did not average over twelve per minute.

The necropsy was performed (by Dr. A. O. J. Kelly) seventy-two hours after death. The body was that of a fairly well-developed female; *panniculus adiposus* slight; the muscular tissues somewhat atrophic. The natural appearances of the tissues and organs of the body were somewhat disturbed, particularly in the direction of excessive dryness, and the serous cavities more or less filled with the embalming fluid. The thoracic and abdominal viscera had their normal positions. The left pleural cavity contained turbid, red fluid. The visceral pleura was firmly adherent to the costal pleura posteriorly and below and to the diaphragmatic pleura. Except some slight deficiency of tissue at the edges, the left lung was normal. There were no evidences of tubercular deposits. The right pleural cavity also contained turbid, red fluid. The two layers of the pleura were adherent posteriorly and below. The upper and middle lobes of the right lung were normal. The lower lobe was rather dense and heavy, but contained air. There were absolutely no evidences of tuberculosis in the lungs. The pericardium contained about 10 c.cm. of clear serum. The heart was much enlarged, the wall of the left ventricle being twice its usual thickness. On the posterior mitral leaflet there was a small islet of thickening. The tricuspid valve leaflets, as far as could be told, appeared normal; the specimen, however, showed such decided *post-mortem* changes that it was impossible to speak positively concerning this. The aortic and pulmonary leaflets were normal. The omentum was normal. The liver was of about normal size; its capsule was normal. On section, the center of the acini was reddish-brown, the periphery more yellowish. The gall-bladder was normal. The spleen was somewhat increased in size and rather dense. On section, it was smooth, dark reddish-brown in color, and showed its capsule and trabeculae thickened. The stomach, pylorus, duodenum, appendix, cecum, and large and small intestines were normal. The left kidney was of about normal size, but denser than normal. Its capsule was here and there somewhat adherent. The surface was mottled in appearance, of a general grayish-red hue, with a few yellowish points alternating with dark-reddish spots. On section, the cortex was normal or slightly increased in thickness. There were yellowish-gray striations, with here and there distinct spots of dark-reddish brown color. The left kidney had two ureters, both healthy. One was smaller than the other, and they joined just prior to their entry into the bladder. The right presented the same general characteristics as the left, save as concerns the pelvis. This was dilated and contained pus. The surface of the pelvis was studded with

about a dozen and a half or more of small miliary tubercles of grayish-white and yellowish color. The ureter was normal. The bladder was healthy. It contained a small amount of pus from the kidney pelvis. The uterus was somewhat atrophic. Attached to its right cornu was a pedunculated fibroid, the size of a goose-egg; on its anterior surface, to the right of the median line, was a small, calcareous fibroid, the size of a small chestnut. The tubes appeared a trifle thickened, but otherwise normal. The ovaries were atrophic. The retroperitoneal glands were normal.

The pathologic diagnosis was chronic diffuse nephritis with tuberculous pyelitis of the right kidney; hypertrophy of the heart; chronic induration of the spleen; nutmeg liver.

A subsequent examination of the pus from the pelvis of the kidney and of that found in the bladder (originally from the kidney) disclosed the presence of tubercle bacilli in both. A microscopic examination of the diseased organs confirmed the macroscopic diagnosis. No disease of the Fallopian tubes could be detected.

This case, therefore, of primary miliary tuberculosis of the kidney is presented as an instance of that rare class of cases characterized by the development of miliary tubercles in but one kidney and unassociated with any other discoverable tuberculous lesion in the body. It is also to be noted that this variety of tuberculosis of the kidney does not of necessity progress to the ordinary or caseous form of primary disease, but that it rather continues as it originates.

Quite distinct from the unusual primary miliary tuberculosis of the kidney is the other and much more common variety of primary tuberculosis of the kidney, the caseous variety. As the miliary, so also the caseous variety, commences in that portion of the kidney to which the bacilli gain access and are arrested. The primary focus is usually in or near the renal papillae, and from here the process spreads to the surrounding renal parenchyma. When the process does not begin in the papillae it may commence in the calices, or in the pelvis of the kidney, or in the cortex; and it is quite probable the cortex is much more frequently the point of departure for the general involvement of the kidney than is commonly supposed. Again, it sometimes seems that, as in the miliary variety, the regions supplied by one branch of the renal artery are, for a time at least, alone affected. The initial lesion being usually situated in the papillae, therefore, it is a matter of but a short time until the tuberculous virus, partly by way of the blood-vessels, partly by way of the lymphatics, and partly, also, by way of the uriniferous tubules, is carried within the substance of the kidney, setting up, at its place of lodgment, lesions similar to those

from whence it came. The process commences by the formation of grayish nodules, which differ from the formations of miliary tuberculosis in their much greater size, and by the tendency they early manifest to undergo caseous necroses. So marked is this tendency that shortly after its formation in the conglomerate tubercle isolated tubercles are frequently impossible of detection. Thus an irregular, softened area is soon formed, and this, by a process of peripheral extension, gradually spreads in all directions, especially toward the cortex. Being near to the pelvis, the latter soon become implicated in the process. The mucous membrane of the kidney pelvis may be the seat of either an eruption of miliary tubercles or of a diffuse tuberculous infiltration. Thus, by an increase in the size of an initial lesion, and by the development of other tuberculous foci, the result of added infection, there occurs a time when the caseous areas spreading toward the periphery implicate the medulla, finally the cortex, and may eventually involve a major portion of the organ.

As these areas degenerate the kidney becomes the seat of irregular, roundish cavities if the necroses occur within the parenchyma of the organ, or of a tuberculous, ulcerating surface if the pelvis be affected. If the process originate in the cortex, as it may, the focus, degenerating, gives rise to a closed cavity. These and other caseous masses within the parenchyma of the organ as they become necrotic are apt to assume a form corresponding to the papillæ—that is, they become pyriform, and, reaching the pelvis, rupture into it. The latter, thus originally encroached upon by the new tissue-formation, increases in size as the necrotic material is discharged into it. It communicates with the several cavities, and one may speak of a *phthisis renalis tuberculosa*. The various cavities are at first separated from each other by walls containing more or less renal parenchyma. Sooner or later these also are involved, become necrotic, break down, and are removed. The kidney is thus converted into a many-chambered cyst, with established communications between the various cavities. These, reaching toward the periphery, are often visible from the exterior, and give to the organ a somewhat bossellated appearance. That tissue nearest the center of the necrotic area is yellowish in color, indicating that here the disease is more advanced and the process degenerating, while that toward the periphery is grayish and of newer formation.

Microscopically, the caseous masses often fail to reveal any vestiges of tubercular formation, justifying the term caseous inflammation or nephritis caseosa, especially as the uriniferous tubules are apt to be found filled with caseous material (proliferated, de-

generated, and caseous epithelium). At the periphery of the caseous masses the nodular make-up of the new tissue-formation is, however, readily recognized, and epithelial cells, giant-cells, round-cell infiltration, and tubercle bacilli are encountered. These latter often are found in greatest number within the uriniferous tubules, by way of which, as already remarked, the process may spread. The process also may attack a minute blood-vessel, and, the caseous matter rupturing into it, thus give rise to extension. The glomeruli are often the seat of round-cell infiltration.

Late in the course of the disease the appearance of the kidney is quite characteristic. It has entirely or in part become converted into a many-chambered sac, the various cavities of which vary much in size and in number, ten to fifteen not infrequently being encountered in one kidney. They usually communicate with themselves and with the pelvis of the kidney—the former by implication and subsequent caseation of the septa; the latter by the rupture into the pelvis of the degenerated foci. So extensive may be the destruction of the kidney substance that the septa may be entirely wanting and the kidney may have been converted into one huge sac, the wall of which will vary much in thickness in different parts. On their inner aspect these cavities are rough and irregular and are covered with a caseous material of a dirty-grayish color. Occasionally one detects appearances suggestive of attempts at healing of a primary tuberculous focus, in the shape of calcareous plates or granules. The contents of these cavities much resemble putty. The cyst or cavity contents are usually of dirty-grayish color. With admixture of much pus they approach a yellowish color, and blood bestows a reddish tint. Not rarely they are serosanguinolent. The cyst contents are of a urinous odor and always deposit a sediment. The latter consists of a cheesy detritus, partially degenerated tubercles, caseous renal tissue, blood, pus, and triple phosphates, less frequently, calcareous matter, phosphate and carbonate of lime, cholesterin, etc.

On external examination the kidney may appear to be of about normal size; or, with preservation of its configuration, it may be moderately or greatly increased in size. The latter is usually observed late in the course of the disease, and is induced by a pyonephrosis secondary to blocking of the ureter. This leads to distention and sacculation of the organ, and finally to complete destruction of all secreting structure. Should one organ only be involved, the drying up of the fluid contents leads to an atrophic kidney, containing inspissated, putty-like masses; or, rarely, one kidney may present an appearance

akin to this, while the other may be of about normal size or greatly distended—the seat of pyonephrosis. The kidney is quite adherent and greatly thickened. Not rarely it forms intimate associations with the perirenal fat—that is, it is well-nigh impossible to separate or distinguish them.

Associated with the disease of the kidney substance, the pelvis usually manifests lesions peculiar to itself. As already alluded to, it may constitute the seat of primary infection. It may thus be affected prior to, simultaneously with, or subsequent to, the kidney lesions. It may be the seat of miliary tubercles, tuberculous infiltration, or both. Originally encroached upon by the increase in size of the kidney by the developing tuberculous new formation, as the caseous foci discharge their contents into it, it augments in volume. It usually is covered with dirty-grayish, putty-like or membranous-like formations, under which or between portions of which, tuberculous ulcerations are common. Late in the course of the affection, with extensive destruction of the kidney and free communication between the cavities and the pelvis, the limits of the latter are usually not determinable. The pelvis usually is dilated from obstruction of the ureter, and contains substances similar to those detailed as occurring in the kidney cavities.

The ureter presents lesions the counterpart of those found in the pelvis. On external examination it may appear distended, but upon section its walls are usually found thickened and its lumen decreased. Its inner surface is irregularly ulcerated and covered with a dirty-grayish or yellowish, membranous-like formation. This, with the thickening of the sub-mucous coat, leads to constriction or obliteration of the lumen and the conversion of the ureter into a more or less rigid tube. Obstruction of the ureter also may be induced by arrested blood-clots or caseous material, be it masses or shreds. The obstruction leads to distention and thinning of the parts above, and consequent dilatation of the pelvis and renal cavities.

When the destruction of the renal parenchyma is well advanced, and the walls of the cavities have become thinned, perforation not infrequently ensues, leading to the formation of perirenal abscesses. These have also been said to be due to lymphatic infection, but this, if it occurs, must be very rare. In general, these abscesses present characteristics similar to those of the renal cavities. They are often made up of irregular, communicating cavities containing material similar to that in the kidney. They extend in all directions, and, though of slow development, may make their way through the diaphragm or into the iliac fossa, or they may even perforate externally.

The bladder is usually contracted, and has thickened walls depending upon hypertrophy of the muscularis and induration of the mucous membrane, which may be tuberculous or not. The mucous membrane may be the seat of an eruption of miliary tubercles or of more extensive tuberculous infiltration or ulceration, particularly at the trigone and fundus, but not uncommonly the tuberculous process terminates at the ureteral orifice of the bladder. It must be mentioned, however, that it has been asserted that the microscope will sometimes reveal tuberculous lesions of the bladder when to the naked eye the viscus appears healthy.

A marked characteristic of this variety of primary tuberculosis of the kidney is the tendency of the other portions of the genito-urinary tract to be implicated in the process—whence the common designation, urogenital tuberculosis. Not rarely both kidneys are found diseased—one, however, usually in a more advanced stage of the disorder than the other. The involvement of the ureter and the bladder already have been referred to. There are often found tuberculous lesions of the testicles, epididymis, vas deferens, or prostate. At times the seminal vesicles alone may be affected. In the female the Fallopian tubes may be the starting-point of a urogenital tuberculosis, but at the same time an uncomplicated urinary tuberculosis may occur. These associations of the renal disease, while not always found, still have important pathologic, clinical, and therapeutic bearings.

(To be continued.)

PRACTICAL REMARKS ON SHOES.¹

By ROYAL WHITMAN, M.D.,
OF NEW YORK.

THE object of the shoe is to cover and to protect the foot, not to deform it or to cause discomfort; therefore the one should correspond to the shape of the other. If the feet are placed side by side, the outline and the imprint of the soles will correspond to the accompanying diagram. The outline demonstrates the actual size and shape of the apposed feet, emphasized by enclosing them in straight lines. Thus, each foot appears to be somewhat triangular, being broad at the front and narrow at the heel. The imprint shows the area of bearing surface, and owing to the fact that but a small portion of the arched part of the foot rests upon the ground, it appears to be markedly twisted inward. The sole of the shoe, if it is to enclose and support the bearing surface, must also appear to be twisted inward in an exaggerated right or left pattern; it will be straight

¹ Read at a meeting of the Harvard Medical Society of New York, May 22, 1897.

along the inner border, to follow the normal line of the great toe, and a wide outward sweep will be

FIG. 1.

Normal feet.

necessary in order to include the outline and thus to avoid compression of the outer border of the foot.

I have found this statement of a self-evident fact and the demonstration of the true form of the foot

FIG. 2.

Proper soles for normal feet.

to be almost an indispensable preliminary to an intelligent discussion of the relative merits of shoes, and, indeed, somewhat of a revelation to those who have thought of the foot only as it has been subordinated to the arbitrary and conventional standard of the shoemaker. This ideal, or shoemaker's foot, upon which lasts are fashioned is much narrower than the actual foot; the great toe is not a powerful movable member, provided with active muscles, but is small and turns outward so that the forefoot is somewhat pyramidal in form, and turns upward as if to avoid the contact with the ground. This imaginary foot, drawn after the shape of the ordinary last, appears in the third diagram. Upon it the sole of the shoe has been indicated (Fig. 4), to contrast it with the shape of that necessary to include the outline of the normal foot. The actual foot is thus compressed laterally by the shoe until the stretching of the leather during

the "breaking-in" process allows it to overhang the sole, the great toe is forced outward, and, with its

FIG. 3.

Shoemaker's feet.

fellows, is compressed, distorted, and lifted off the ground by the rocker-shaped sole, so that normal

FIG. 4.

Shoemaker's soles.

function is reduced to the smallest limit. Thus, the foot, according to the age at which the reshaping

FIG. 5.

The rocker sole.

process is begun and the constancy of the application, gradually approaches the ideal and fits the shoe.

This remodeling, however, is often accompanied by such discomfort that the individual rebels and wears a shoe with a square toe, which, from the conventional standpoint, is supposed to show a meritorious effort to follow Nature; but the demonstration of

the actual foot makes it evident that it is a properly shaped sole which serves as a support, not the part which projects beyond the foot, that is of importance. If the shoe with the square toe is wider and straighter on the inner side than another with a pointed tip, it is in so far an improvement; but, as a matter of fact, one of the worst types of shoe provided for children, in shape very like the old-fashioned coffin lid, owes its popularity to the square toe. The same comment may be made on the so-called "common-sense shoe," which is well named,

FIG. 6.

Skiagram of a foot modeled to fit the shoe.

since it may be assumed that a properly shaped shoe is an evidence of uncommon sense.

The object of the heel is to make walking easier by inclining the body somewhat forward. The high narrow heel is an insecure support, and aids deformity by throwing more strain upon the forefoot and pushing it forward into the narrowest part of the shoe. The heel is of course unnecessary in childhood, and should not be worn, since it limits the necessity for, and therefore the use of, the normal range of motion at the ankle-joint. The ordinary shoe, by limiting the functional use of the foot, favors awkwardness

in gait and attitude; it compresses the toes, and is directly responsible for corns, bunions, ingrown toenails, and deformities, and indirectly it causes or aggravates nearly every weakness to which the foot is liable. This assertion does not need the support of argument, since in some degree it has been proved by the personal experience of every shoe-wearer.

The shape of the proper shoe corresponding to the undistorted foot has already been demonstrated. The sole should be thick enough for protection, but not so rigid as to limit normal motion; it should follow the imprint of the foot, projecting somewhat beyond the outline of the toes; it should be flat, and the upper leather should be capacious—in other

FIG. 7.

The flat sole.

words, the front of the shoe should be designed to allow and to encourage functional activity, the slight adduction of the great toe and the alternate expansion and contraction of its fellows, as may be observed in the barefoot child. Thus the arch may be assisted, and the weight and strain properly distributed. The heel should be broad and low.

The shape of the shoe is regulated by fashion and ancient custom, although it has been spoken of as the shoemaker's ideal for convenience of description. Shoes are made to sell, and if better shoes were desired they would be produced; but long familiarity with discomfort and deformity has distorted the public taste so that deformity is not only not recognized as such, but when concealed in the shoe it is illustrated as a type of beauty.

Reform in shoes will be a gradual process, and it will come through the conversion of the individual. Conversion is not enough, however; one must not only be convinced that his shoes are bad, but he must be informed where better ones may be obtained. Thus practical reform must begin with education of a shoemaker, and the displacing of some of his inherited or accumulated lasts by those of a better model. This is not an easy task, but my experience proves it to be possible. It has been said, with truth, that physicians are not consulted on the subject of shoes, but, on the other hand, it must be remembered that the foot has long been abandoned to the shoemaker and corn-doctor, and it is only during recent years that any particular or general interest in its diseases or disabilities has been manifested. Even

at the present time it may be doubted if the shoes worn by physicians themselves will show great advance or improvement over those worn by others less familiar with the anatomic construction of the foot. It would seem, however, that such knowledge should make one better able to appreciate the bad effects of compression and deformity and the more willing, therefore, to set an example to others. This is of importance, because every wearer of a better shoe becomes a reformer involuntarily, if only to justify the shape of the shoe he wears; and the physician, in addition, will find many opportunities to select or to suggest the selection of the better from the worse type of shoes which are provided, even if no radical change is desired or attempted. In such selection, the breadth of the sole, the angle of outward deviation of the soles when the two are placed side by side, and the capacity of the upper-leather must be the determining points. As a rule, what is known as the wide Waukenphast pattern for men and children will be found the best, and even the shoes made for women will permit of reasonable choice. Nearly all adult feet are more or less deformed, and therefore better adapted to an improved than to a perfect shoe. Moreover, it is by the more extended use of the better type of shoe, such as is now made by the more intelligent shoemakers, that a general advance may be anticipated.

It is encouraging to note that the foot, once allowed a certain freedom, resents most effectively a return to restriction and compression, and that the deformed foot shows a marked tendency toward improvement when a shoe is provided which allows the long disused muscles to exercise their function—a fact which is of great importance in the treatment of actual disability.

The most effective work for reform can be accomplished by providing better shoes for children; and especially since one encounters inertia, rather than active resistance, most parents have suffered sufficiently to be willing to permit the child to wear a proper shoe, even though it may offend their conception of beauty and symmetry. The inspection of children's feet shows that atrophy and compression begin at a very early age, and if protection might be assured during the period of rapid growth, serious distortion might be prevented.

Although of far less importance than the shoes, the socks worn by children deserve special mention as a factor in deformity, since they are often too short and too narrow and are made of unyielding material, so that the proper action of the toes is restrained. Theoretically, the socks, like the shoes, should be rights and lefts, but if they are sufficiently large and of a texture to expand readily to the shape

of the foot, but little trouble need be anticipated on this score.

In conclusion, it is again urged that there can be but one standard upon which the shoe can be judged, and this standard is the undistorted foot; therefore, the sole of the shoe, whether it be oblong or triangular, whether the tips be round or square, or whatever may be the minor variations, must be long enough and broad enough to support the foot, and the upper-leather must be capacious enough to contain it without compression of the toes. If one is interested in reform, he must find a shoemaker willing to make proper shoes for perfect feet, or, having ascertained the best type of the ready-made shoe, this only should be recommended. It may be assumed that manufacturers of the cheaper shoes are sensitive to changes in demand, and that with little effort on the part of physicians and others an improved, or even proper, shoe might be found on sale side by side with that of the conventional model, and for the same price.

Reform must be made simple, it must be inexpensive and, in fact, involuntary to be effective. Gradually, however, it may be hoped that the shape of the natural foot will displace that of the conventional model, so that deformity may be recognized; then the fact that the foot must give distinction to the shoe, and not the shoe to the foot, will be established.

**THE USE OF IODOFORM IN SUPPURATIVE
CERVICAL ADENITIS, SINUSES, ETC.,
WITH A REPORT OF SIX CASES.¹**

BY D. ERNEST WALKER, M.D.,
OF NEW YORK.

DURING the summer of 1896 a number of children came under my care who were suffering from glandular affections of the neck arising from a poor general condition, which were accompanied in a few cases by a tuberculous diathesis. With few exceptions all of these cases had reached the suppurative stage, and in most of them satisfactory excision of the glands was out of the question.

Up to the middle of June I had treated the suppurative cases by free incision, afterward washing out the cavities with antiseptic solutions, usually carbolic acid or bichlorid of mercury, and in some cases peroxid of hydrogen. Then, if drainage was considered necessary, iodoform gauze generally was used. The abscess cavities were not curetted, but were carefully swabbed out with cotton wet in the antiseptic solution. The trouble experienced from the refilling of cavities which were not drained, and the redressing of those which were, as well as the slowness with

¹ Read before the Society of the Alumni of the City (Charity) Hospital, April 7, 1897.

which some of them healed, led me to cast about for some method which would prove less troublesome. I therefore determined to try a ten-per-cent. iodoform ointment made up with vaselin, as used in suppurative buboes, concerning which Dr. Otis¹ has written so favorably. I confess that at the time I felt somewhat dubious as to the safety of employing a ten-per-cent. iodoform ointment in the case of a child, but decided to use it as no ill effects had been reported in any similar case. I was also influenced by the fact that the abscess in the first case in which I decided to employ the remedy was a small one.

CASE I.—This was a female child, fourteen months of age, with a good family history, but in poor general condition. The child was anemic, but not thin, and her flesh was flabby. There was an acute adenitis on the right side of the neck accompanied by heat, redness, and pain. There was also a swelling on the left side of the neck. Both enlargements were among the submaxillary group of glands, and that on the right side was softened at the apex. That on the left side gave no signs of suppuration.

After first washing the neck with soap and water, and then with bichlorid of mercury solution, 1 to 4000, I made a small incision into the apex of the abscess on the right side of the neck, evacuated about half an ounce of pus, and carefully washed out the cavity with the 1-to-4000 bichlorid solution. Then, with a glass syringe previously warmed in hot water, I filled the cavity to slight distension with a ten-per-cent. iodoform ointment, and placed immediately over the opening a cotton compress wet in cold bichlorid solution. Over all was placed a simple dressing of borated cotton. After two days I refilled the cavity, from which there was only a slight serous discharge, and five days later the abscess was completely cured. On the fifth day I opened the abscess on the left side, which in the meantime had become inflamed and painful. It contained about one dram of pus, and required but one treatment, healing completely in four days.

CASE II. was that of a female child, five years old, with a tuberculous adenitis, who was brought to my office by a professional friend to whom I had spoken of the previous case. One gland among a mass of others on the right side of the neck was red and soft at the apex, but there was no heat or pain. I pursued the same method as in Case I. evacuating a dram or two of curdy pus, washing out afterward, and filling the cavity as before. The cavity closed completely in five days, after being refilled once. Another gland among the mastoid group, which softened a few days later, was treated in the same way and speedily healed without being refilled.

CASE III. was that of a middle-aged man whom I saw in consultation with Dr. Holmes. He had an acute adenitis affecting the deep cervical glands. There was a large swelling on the left side of the neck which displaced the *pomum Adami* far to the right. There was some edema, but no perceptible

fluctuation. A slight softening could be detected at the anterior border of the sternocleidomastoid muscle at the side of the larynx. The attack had been ushered in by a chill and severe pain.

When seen there was marked heat and redness, but not much pain. The patient's temperature was slightly elevated, and his general condition was much below par. Immediate operation was advised, and under ether I made an incision through the skin and fascia. Deep in the region of the carotid an ounce or more of pus was found. The cavity was treated in the same manner as in the previous cases, and it closed completely in six days. It was refilled once.

CASE IV.—An adult female, a patient of Dr. Holmes, while convalescing from typhoid fever developed a large abscess in the gluteal region, which, owing to her prostrated condition, was not noticed by the nurse until it was on the point of bursting. It opened spontaneously before the doctor had an opportunity to incise it. The cavity extended among the gluteal muscles to a depth of about four inches. After thorough disinfection it was filled with ten-per-cent. iodoform ointment, and after this was repeated twice cure was complete.

CASE V. was one of mastitis, in a woman about twenty-five years old. An abscess containing about half an ounce of pus had pointed near the right nipple. Results had been so satisfactory in other abscess cases that the iodoform treatment was tried in this one with complete success after one refilling.

I previously had tried to induce a friend to adopt this procedure in a case of mastitis which I saw with him, but as he feared absorption and poisoning, the abscess was opened freely and drained by means of gauze. Recovery was very slow.

CASE VI. was that of a middle-aged man whom I saw with Dr. Mowry. It was a severe case of cellulitis following a wound in the calf of the leg inflicted by the teeth and claws of a cat. There was so much destruction of cutaneous tissue and so many sinuses to be laid open that when the inflammation had somewhat subsided we determined to try the iodoform ointment treatment in two large sinuses running upward beneath the skin toward the popliteal space. These were so extensive that a five-per-cent. ointment was used. The smaller sinuses closed after two treatments, but in the others there seemed to be no improvement except in the amount of the discharge. After a few trials, therefore, this treatment was discontinued and the cavity packed as before with iodoform gauze. After a few more days, with no perceptible improvement, a large slough was drawn out from the cavity, which was again filled with the ointment, with most happy results. The cavity easily held an ounce and was not refilled afterward.

The general procedure, while it differed in some particulars from the iodoform treatment of bubo, was practically the same in all these cases. The parts were carefully cleansed and disinfected, and, after making a small incision, cavities were thoroughly washed out with a 1-to-4000 solution of bichlo-

¹ Amer. Jour. of the Med. Sciences, May, 1893.

rid of mercury. In one case, carbolic solution, 1 to 100, was used. All pyogenic material was carefully expressed. The cavity or sinus was filled to slight distention with warm iodoform ointment, and a compress wet with cold bichlorid solution was placed immediately over the opening in order to solidify the ointment. A simple aseptic dressing was then put on, care being taken not to make sufficient pressure to force out the ointment. This dressing was not removed in any instance until two or three days had elapsed unless it became soiled with discharges from the wound, and in no case except No. IV. were more than two applications made. I cannot say that a second dressing was necessary in any of the other cases, except in one in which there was a little pus found when the first dressing was removed. In all of the others there was only a slightly colored serous discharge, which always seemed to me to be a sign of success. I refilled the cavity in those cases in which there was any discharge, simply to prevent possible closure of the external wound by any pus remaining in the cavity.

The advantages of this plan over the usual methods of treating suppurative adenitis in children seem especially worthy of note. The methods generally employed are: (1) Simple incision with or without drainage; (2) excision or enucleation; (3) scooping or curetting; (4) cautery puncture. All of these, except the first, usually require the administration of an anesthetic, and all are liable to leave a wound which heals slowly by granulation. In addition, all have a tendency to leave disfiguring scars, and in all, redressing, when drainage is employed, is very troublesome.

The advantages of the iodoform treatment may be summed up as follows: (1) Its simplicity. (2) Its easy application. (3) The avoidance of troublesome redressings. (4) The small incision required and the small resulting scar. (5) The rapidity of the reparative process. The employment of this method in the treatment of mastitis, and in troublesome though simple sinuses, and in pyogenic tracts in which it is difficult to secure good drainage, seems worthy of further trial. It is important to bear in mind, however, that any sinus or cavity which contains anything of the nature of a foreign body, such as sloughs, necrotic bone, etc., are apparently not benefited by it.

I question whether absorption is sufficiently rapid in pyogenic tissue to cause iodoform poisoning from the use of a ten-per-cent. ointment. Certainly no symptoms of poisoning occurred in any case which came under my notice, and I used as much as one ounce of the ointment on several occasions. A five-per-cent. ointment acted just as well as one of ten-

per-cent. strength in the one case in which I employed it, and in a majority of instances a still weaker combination probably would be successful. Abscess cavities or sinuses should not be curetted, as this but adds to the danger of absorption of the drug and consequent poisoning.

My experience has led me to believe that this treatment may prove of great value in certain cases of empyema, though one would be inclined to fear that absorption of the drug would be so great that its use would not be permissible. Should it succeed in this affection, one might speculate on its possibilities in the treatment of pelvic abscess or abscess of the liver.

Since this paper was written I have learned that Wieland¹ has reported twenty-one cases of tuberculous abscess treated by routine injections of iodoform in sterilized oil or glycerol, ten per cent., with sixteen cures. Four of his patients developed symptoms of iodoform poisoning.

PENETRATING WOUNDS OF THE LIVER; REPORT OF A CASE.

BY JAMES KERR, M.D.,
WITH THE COLLABORATION OF
J. H. FORD, M.D.,
OF WASHINGTON, D. C.

ON November 10, 1894, at 7.30 P. M., J. C., aged twelve, colored, male, was brought to the Emergency Hospital suffering from a gunshot wound of the abdomen, which had been received half an hour before, the weapon being a 22-caliber rifle. Upon admission, shock was marked and there was great pain and tenderness over the epigastrium. The pulse was rapid and feeble, and the respiration, thoracic in character, was shallow and quick. The pupils were dilated and the temperature subnormal. There was no nausea or vomiting. Two wounds were found, that of entrance, between the eighth and ninth ribs, on the right side, and 6 cm. to the outer side of the nipple, and that of exit, 7 cm. above and to the left of the umbilicus. Through the latter a piece of omentum 4 cm. in length protruded.

The boy immediately was treated for shock, $\frac{1}{4}$ th of a grain of strychnin and $\frac{1}{16}$ th of a grain of morphin being administered hypodermically, with whisky by the mouth and the external application of heat. At nine o'clock he was placed on the operating-table, the abdomen prepared, and an incision made from the umbilicus upward for 15 cm. The protruding omentum was drawn through the wound of exit, clamped, ligated with silk, and cut off. A large clot was found on the surface of the liver. The left lobe was lacerated for 12 cm., the wound extending across the notch. There was free hemorrhage from this and from the opposing surfaces of the notch, which was controlled by the application of compresses wrung out in very hot salt solution. The laceration was sutured with silk.

¹ *Deutsch. Zeit. f. Chir.*, xli, 4, 5.

The probability of extreme shock having been recognized at the outset, the patient had been covered with hot blankets and surrounded by hot water bottles, and as the pulse and respiration were now failing rapidly, transfusion was resorted to and continued until the operation was completed, about two liters of normal salt solution being injected into the left median basilic vein.

The abdominal incision was then extended from the xiphoid cartilage to a point 6 cm. below the umbilicus, and the parietes being well retracted, a wound 20 cm. long was found across the convex surface of the right lobe of the liver, extending, as did the one in the left lobe, to a depth of from 3 to 5 cm. This wound also was sutured and about a quart of hot salt solution poured into the abdominal cavity, and, with the effused blood, allowed to remain. The patient reacted well and was sent to the ward with good pulse and respiration. His recovery was jeopardized by what appeared to be simple intestinal paralysis following the operation, which only yielded to very brisk purgation. With that exception he made an uninterrupted convalescence. The wound was dressed on the tenth day and the sutures removed.

The features of the case which appear to be most important are (1) the early operation, just as soon as the shock of the accident justified it; (2) the provision for carrying out transfusion while the operation progressed; (3) the immediate control of hemorrhage after having rapidly opened the abdomen and compressed the bleeding surfaces, and the permanent control of the hemorrhage by sutures. The sutures were introduced by means of a large, full-curved needle well back from the edges of the wound.

The operation was as rapidly conducted as was compatible with carrying out the various procedures mentioned. No effort was made to clear the abdomen of clots. During the exposure of the wound in the liver it was necessary to divide the falciform ligament. This was not sutured, and the wound in the parietes was closed with as few sutures as possible.

The following summary is made from the available literature on the subject of wounds of the liver and may be averaged thus: Total number of cases, 51; recovered, 33; died, 18; mortality, 35.2 per cent.

Since in four of these cases no operation was performed, a table showing the mortality of the remaining cases would stand thus: Number of cases operated on, 39; recovered, 26; died, 13; mortality, 33.3 per cent.

I have had reports collected of thirty-nine cases of wounds of the liver which were treated either by gauze tampon, sutures, or the Paquelin cautery. These statistics, like those given above, show the greater desirability of suturing in these cases.

Method employed.	Number of cases.	Recovered.	Died.	Mortality, per cent.
Sutures only.....	24	17	7	29.1
Gauze tampons only.....	4	1	3	75.0
Sutures first, but when these tore out gauze tampons ¹	83	1	2	66.6
Unclassified methods.....		7	1	12.5
Tube inserted in track of wound after being wrapped in gauze.....	1	1	0	0
Gallic acid administered and lower chest strapped tightly with adhesive plaster.....	1	1	0	0
Drainage tube inserted into wound of entrance.....	1	1	0	0
Incision to remove contained pus. Drainage.....	1	1	0	0
Drainage tube along entire track of wound.....	2	2	0	0
Removal of fluid in peritoneal cavity. Drainage wounds of entrance and exit by gauze.....	1	1	0	0
No operation employed.....	4	0	4	100

Method employed.	Recovered.	Died.	Mortality, per cent.
Gauze tampon.....	5	8	61.5
Cautery.....	2	2	50.0
Sutures.....	15	7	31.1

The mortality, respectively, of treatment by suturing and tamponing (the two most popular methods), as deduced from the aggregation of cases so treated in this and the preceding table, is as follows:

Method employed.	Number of cases.	Recovered.	Died.	Mortality, per cent.
Gauze tampons.....	17	6	11	64.7
Sutures.....	46	32	14	30.4
Average mortality of the two methods.....				38.1

Edler deduces the general mortality of liver wounds in 543 cases (no treatment specified), as 66.8 per cent. It is probable that in some of these either the hepatic wound was not treated or was complicated by injuries to other viscera. Mayer finds that the mortality in 61 cases of gunshot wounds which he studied is only 34.4 per cent. Otis, in the "Medical and Surgical History of the War of the Rebellion," mentions 173 cases of gunshot wounds of the liver. His data may be presented thus:

¹ In one of these cases (which terminated fatally) Paquelin's cautery was employed after the sutures tore out and before the wound was tamponed.

Nature of injury.	Number of cases.	Recovered.	Died.	Mortality, per cent.
Liver injury dominant.....	59	25	34	56.9
Other organs also injured.....	114	37	74	64.9

Thus it would appear that liver wounds should be treated by suturing, but undeniably there are many cases in which this method is impracticable and treatment by tamponing or the cautery is the only resource. There are many factors influencing the treatment of any given case which are not brought out in sufficient contrast in tables, and the aggregation of cases which differ in a vast number of essential details but agree only in one will leave great opportunity for error if the deduced statistics are referred to as conclusive. Only from very large tables, containing cases representing a great variety of conditions, can a really fair estimate of the comparative values of different methods of treatment be obtained; for in these the characteristics which are peculiar to each case cancel each other in the aggregate. But, as in the present instance, in which one method shows little more than half the mortality of another, there cannot be much hesitancy in arriving at a conclusion in its favor. Hence, in the *average* case of penetrating wounds of the liver sutures should be given the preference, but instances will be found in which sutures alone are insufficient.¹ Cauterizing alone has little effect upon hepatic hemorrhage because of the extreme tenuity of the vessels and the great vascularity of the organ. The larger vessels are more harmed than benefited by contact with the cautery; they should be ligated separately, but if they are inaccessible and bleeding freely it is best to tampon the wound. The mortality of this procedure is high, but it is less than that of other methods under the same circumstances. It is this class of wounds, generally caused by a bullet, that gives to the gauze tampon-treatment such a high mortality. If the wound is suitable for the insertion of sutures, they should be introduced at some little distance from the edge ($\frac{1}{3}$ to $\frac{1}{2}$ an inch) and must not be drawn tighter than merely to cause contact at the site of the hemorrhage.

In all cases the operation should be performed at

¹ Clementi ("Immediate Ligation of Vessels in Wounds of the Liver," Roma, 1892) seared the bleeding surfaces of the wound, ligated the larger bleeding vessels separately, and sutured the wound. Hemostasis was perfect. He also obtained excellent results from compression with tampons alone, and found that in very deep wounds they acted better than sutures, being in more exact contact with the bleeding surfaces. If bleeding is from a deep vessel the sutures in the lips of the wound cannot hold the bleeding points of the wound close enough together to permit them to act as autoplastics. If the larger vessels are ligated cauterization can well be dispensed with.

the earliest possible moment. As with injuries of other viscera, the two most important factors which determine the time of operation are shock and hemorrhage. It is not advisable to operate until the patient rallies perceptibly from shock; to do so would be merely to pile Ossa on Pelion; but because of the sometimes continual uncontrollable oozing of blood from the wound, and the increase of capillary hemorrhage as the heart becomes stronger, it will be well to operate while the patient is in a condition which might be regarded as hazardous in the case of many other major operations. The usual restoratives should be administered, and to check this free hemorrhage until the time of operation, gauze should be introduced at the earliest moment and, when possible, packed into the wound. The hemostatic effect of this treatment is excellent, and the patient will be in a much better condition at the time of operation than if other anticipatory measures are employed. Before, during, or after the operation, when all bleeding has been checked, transfusion will often save the patient's life.

Babacci ("Elastic Sutures of the Liver," Pansula, 1889), from a long series of observations on dogs, concludes that the only treatment justifiable in cases of wounds of the liver is suturing, but so broad a conclusion is unwarrantable. One suggestion that he makes is excellent, *i. e.*, the employment of an elastic suture; it is to be sanctioned for many reasons: (1) It is perfectly supported by the animal tissues and the part of the liver which encapsulates it. (2) It can be threaded in a needle smaller than its own diameter by cutting it obliquely. (3) It enters the wound in the hepatic capsule with facility (if a round needle be employed) because its elasticity renders it slender when it is drawn through the tissues, and when traction stops it thickens and perfectly fills up the hole through which it has passed. (4) Unlike other threads, it does not rub or saw in its passage; it lacerates less and passes more easily, and is less liable to cut its way out. (5) In the liver, an organ subject to great normal oscillations in volume, the elastic suture causes less tension than does any other, for it yields before congestion, yet holds the surfaces apposed when the organ shrinks. These two last facts are the ones which compel its use to be sanctioned. Elastic sutures should never be fastened with knots, but the ends should be doubled over upon themselves about $\frac{1}{2}$ cm. and tied with silk or fine catgut, while held close to the edge of the tissue.

Chinese Woman Doctor.—The Siang-Hu Hospital in Foo Chow, China, is in charge of a Chinese woman doctor—Dr. Hu King Eng, who received her medical education in the United States.

CLINICAL MEMORANDA.

CONGENITAL OCCLUSION OF THE RECTUM AND ANUS; REPORT OF A CASE SUCCESSFULLY OPERATED UPON THROUGH THE PERINEUM.

BY A. P. STONER, M.D.,
OF CAINSVILLE, MO.

THE rarity of congenital malformations of the rectum and anus renders a report of a case both interesting and profitable. In 16,654 births at the Dublin Lying-in Hospital, Collins¹ observed but one case, and Zöhrer of Vienna found but two instances in 50,000 births. Wharton² places the average number of these malformations as about 1 case in 10,000.

At an early period of embryonic life the apertures of the primitive intestine are formed. Simultaneously with the formation of the nasal and oral cavities a depression occurs at the caudal extremity which deepens into a pocket, and this finally connects with the gut to form the rectum and anus. Should there be an interruption of this process, and a failure of communication between the two pouches, an occlusion of the rectum or anus, or both, results. A thin membrane only may exist between the outer cul-de-sac and the caudal pouch at birth, there being an appearance of a normal opening. Other cases present a depression at the anal site and the rectum ends high up, the intervening space being filled with cellular tissue. In other cases of malformation the rectum is found low down, being occluded only by a diaphragm of well-formed skin.

Cases have been noted in which there was an entire absence of the rectum. The bowel sometimes communicates with the vagina, bladder, or urethra. A few cases also have been reported of congenital narrowing of the rectum without complete occlusion, and Wharton refers to a case reported by Amussat in which the anus was well-formed, but communicated with the vagina, while the rectum ended in a cul-de-sac.

Given any of the above conditions, the question arises as to what, if anything, should be done for its relief. Matthews, in his excellent work on "Diseases of the Rectum," takes a decidedly pessimistic view of operative interference, and cites Cripps to substantiate his opinion. He says: "It has been seriously discussed by intelligent people whether life is worth living at the best. Surely, under the conditions which would exist after either one or the other of the operations suggested for such malformations, life would be anything but worth living." On the other hand, there are a number of well-attested cases of cure after operation, the patients enjoying useful lives, and I believe the general consensus of opinion among our best surgeons is that the operation is always justifiable. Cripps has collected reports of 100 cases in which an operation has been performed, with a mortality of but fifty per cent. When we consider that these patients were operated upon in pre-antiseptic days, there is little reason to doubt that under our present perfected aseptic technic better results may be obtained. These patients, if left

alone, die either from peritonitis caused by rupture of the bowel or from general marasmus.

But two operations for the relief of these malformations are now recognized, *viz.*, incision through the perineum (the rectum being brought down and attached to the natural anal site), and left inguinal colotomy. Authorities are now well agreed that preference should always be given to the perineal operation, and I am under the impression that it is possible to reach the gut by this route in the majority of cases. In substantiation of this assertion, Lanphear¹ has reported the case of a patient successfully operated upon in this way, there being a total absence of the upper rectum. "An incision was made through the sphincter to the coccyx, and the dissection carried through the connective tissue to near the promontory of the sacrum. A small sound was inserted in the bladder as a guide, and after dissecting upward for an inch and a half the peritoneum was reached. This was cut into, and the sigmoid flexure of the colon easily pulled down and stitched to the upper end of the rectum, an opening three-quarters of an inch long being made in the side of the bowel, with a discharge of an immense amount of feces. There has been no fever and no peritonitis, and the child is well and growing nicely."

In preparing for operation through the perineum the left groin should also be prepared, so that in case the gut is not reached by the former route, a colotomy may be performed.

In the report of the following case, which occurred in my own practice, I include the technic of the operation in full:

On June 10, 1896, at 7 A.M., Mrs. L. gave birth to her first child, a male, weighing 7½ pounds. After the child was given to the nurse it was noticed that the right ear was rudimentary, it being about one-third the size of the left. This led to a further examination, which resulted in the discovery that there was a total absence of the anal orifice. There was nothing whatever to mark the original intention of Nature—no crease, not even a raphé dividing the nates, the whole buttock being one firm, smooth, rounded mass, giving the impression of solid muscular tissue beneath the skin.

Operation being decided upon, the child's body was at once thoroughly scrubbed with soap and warm water, bathed with a 1 to 1000 mercuric bichlorid solution, and afterward wiped dry with sterilized gauze and enveloped in a thin layer of corrosive sublimate cotton, 1 to 2000, held in place by a bandage. The child was brought to the operating-room at 2 P.M. and was again thoroughly scrubbed with green soap, and afterward rinsed with sterilized water, after which it was rubbed with a wad of sterilized gauze saturated with alcohol, the belly and perineal region receiving especial attention. It was again rinsed with a 1 to 1000 bichlorid solution and laid upon a pad of sterilized towels on the operating-table. But a few drops of chloroform were inhaled at the beginning of the operation—only enough to blunt sensibility while the incision was being divided.

With the patient in the exaggerated lithotomy position,

¹ "System of Midwifery," page 509.

² "American Text-Book of the Diseases of Children."

¹ "American Text-Book of Obstetrics."

an incision was begun near the scrotal margin of the perineum and carried back to the tip of the coccyx, keeping as nearly as possible to the median line. This was cautiously deepened, and after a depth of three-quarters of an inch had been reached it was prolonged backward along the left margin of the coccyx, and the dissection made to hug the sacrum, in order to avoid wounding the bladder. I now exchanged the small scalpel I had been using for a medium-sized tenotome, reversed the cutting edge, and gradually separated the tissues with the back of the blade, alternately using the handle of the knife for the same purpose as the wound was deepened, the walls being held apart by retractors in the hands of an assistant.

When a point about $1\frac{3}{4}$ inches from the surface was reached, a slight bulging could be perceived when the child cried. As the dissection was deepened, the bulging became more and more perceptible. No chloroform was given after the primary incision was made, and the pain apparently was so slight that I felt almost tempted to resort to some additional means to cause the child to cry, for I found this to be a decided help in locating the gut. When a depth of about two inches was reached, the bowel was brought into view. There was nothing in its appearance, however, to distinguish it from its neighboring viscus—the bladder.

The handle of the scalpel was then used, in connection with my finger, to separate the gut from the surrounding tissue, and at each cry of the child it was made to descend nearer to the surface. The smallest-sized trocar and cannula was then introduced into the center of the bulging mass, to make sure that it was the bowel, and when the trocar removed there was an escape of gas of characteristic odor. The cannula was removed, and a pair of catch forceps applied to the bowel over the opening made by the trocar, thus effectually closing it and preventing the escape of fecal matter into the wound. Gentle traction was now made on the forceps while the adhesions were being broken up. After considerable manipulation the intestine finally was brought to the surface. While the forceps was still in position an incision one-half an inch in length was made into the bowel, and a very large amount of meconium evacuated.

The edges of the incision in the bowel were then stitched to the integument, four fine silk sutures being used on each side. The forceps being removed, the incision was carried forward one-quarter of an inch further, making the bowel incision three-quarters of an inch in length. This likewise was stitched to the integument, thus making six sutures on each side. The perineal wound was closed by deep and superficial sutures and sealed with iodoform-collodion. Iodoform gauze and plain cotton completed the dressing.

The child rallied nicely. Time of operation, fifty-five minutes, much time being lost in waiting for the meconium to escape. No hemorrhage was encountered during the operation, not an artery having been severed.

The following notes from my case-book show the progress and after-treatment:

June 11th. Wound dressed three times. Soiled by feces twice. Evening temperature 99° F. Nurses well

and appears to be doing well. Somewhat icteric. June 13th. Rested well during the night. Morning temperature 100° F.; nurses eagerly. Much annoyance is caused by the urine and feces infiltrating the wound. No indication of primary healing except in front of gut attachment. June 15th, 8 A.M. Temperature 104.5° F. Wound appears healthy. Rested badly during the night. Nurses poorly; 4 P.M., temperature 100.5° F. Appears to be improving. June 16th. Morning temperature 100° F. Slept all night. Icterus disappearing. Most of the rectal stitches have cut through but the gut has not receded more than a quarter of an inch. That part of the perineal wound posterior to the gut attachment having failed to heal, the stitches were removed, and the wound packed with gauze. Some tympanites present.

June 20th. Temperature normal. Icterus has disappeared. Primary union obtained anterior to the gut attachment. Posterior wound closing nicely, with healthy granulations. No tympanites. June 26th. Child doing well except for an occasional rise of temperature. July 6th. Has been suffering some from constipation and strains while the bowels are being moved. A trace of fecal matter was forced through the urethra. Wound has closed, and the opening in the bowel is being dilated daily with soft rubber bougies, there being a tendency to contraction, the opening having become somewhat rigid.

The patient passed from under my observation about November 1st, at which time bougies were being passed once or twice a week in order to prevent any undue contraction of the new anal orifice. There was a decided tendency toward constipation, principally owing to the carelessness of the attendants. The child was well nourished. The nates were distinctly marked and the anus presented a natural appearance. On several occasions a trace of fecal matter was passed by urethra, which indicated that the rectum communicated with the urethra or bladder. It seems highly probable, on account of the high situation of the rectal pouch, that the communication was by a minute opening into the latter. The child had full control over the sphincter, there being little or no incontinence five or six weeks after the operation. I am informed that the child is still well and doing finely, and has no incontinence.

ARTERIAL VARIX OF THE LOWER LIP, INVOLVING THE CORONARY ARTERIES: EX-TIRPATION UNDER COCAIN ANESTHESIA.

By RUDOLPH MATAS, M.D.,
OF NEW ORLEANS, LA.;

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF TULANE UNIVERSITY.

ACQUIRED aneurismal disease or varix of the coronary arteries must be a very rare condition when we consider the ample provision made by nature to prevent undue stretching of the arteries in this particular area. The arteries of the face, as we know, are normally tortuous and wavy, in order to allow for the continuous mobility of the face and the almost incessant exercise of the muscles which are brought into play in the formation of expression, in mas-

tication and in vocalization. The lips, in addition to being highly valuable prehensile organs, are indispensable in the exercise of many musical and other vocations. Of those that require the mastery of special instruments there are few which more seriously tax the muscular and circulatory apparatus of the lips, especially the more mobile lower lip, than cornet playing. In performing upon this instrument not only is a certain configuration and thickness of the oral orifice very desirable but almost necessary. The lips must adapt themselves to the mouthpiece of the instrument and not the mouthpiece to the lips. While playing, the lips are firmly compressed by the circular edge of the mouthpiece, and in this way the mucous membrane is gradually forced and prolapsed into the narrow funnel. By the combined pressure of the metallic rim and protracted constriction of the circular sphincter a condition of corrugation and puckering, followed often by slight edema of the projecting mucous membrane contained in the mouthpiece takes place, which is very striking to any one who will remember the appearance of the mouth of a cornet-player immediately after a long performance. This puffy and edematous condition is, in fact, necessary for effectual playing in some cases, and, if I am not mistaken in my information, it is cultivated by professional musicians, who often practice with the sole view of adapting their mouths to their work whenever any especially difficult performance is expected of them. Nevertheless, arterial disease of the lips as the result of cornet-playing is certainly a rare condition: at least I know of no instances similar to the one which I report herewith. I have made no special inquiry upon the subject, but numerous systematic writers whom I have consulted fail to mention arterial varix of the lip as a sequel to this or any other mode of labial exercise or traumatism.

During the summer of 1895 I was consulted by Mr. J. W., forty-two years of age, a professional cornet-player in one of our local theaters, on account of a peculiar pulsating swelling which affected his lower lip. About seven months before consulting me he noticed that his lower lip "throbbed" considerably after any long performance upon his instrument, and that the lip remained slightly swollen for some time after he had ceased playing. He did not pay much attention to this at first, but the throbbing became so persistent that it annoyed him. It was scarcely perceptible after a few hours' rest, but it always recurred immediately after playing. As there was no pain or positive evidence of inflammation he did not seek advice until he realized that the condition ultimately would disable him. When he consulted me his lip presented, externally, a perfectly normal appearance. Upon stretching the lip and examining its inner surface I recognized a slight elevation in front of the frenum labii, which pulsed very distinctly. By pressing the lip between the thumb and index-finger the existence of pulsation was confirmed and its area of distribution distinctly traced out toward the commissures. The cause of the trouble evidently was an enlarged coronary artery which was especially dilated at the usual point of anastomotic communication in the middle line. The enlargement at this point caused the usually

small and invisible coronaries to feel as large as the facial artery itself. The course of the dilated vessel could be distinctly traced in the submucous tissue by simply stretching the lip and passing the pulp of the finger gently over the surface. It was evident that it was the inferior coronary circle which was enlarged and that a few other collateral vessels participated in the dilatation.

I decided to cocaineize the lip and extirpate the dilated arteries. A 1-per-cent. cocain hydrochlorate solution (at that time the use of Schleich's weak solutions had not been introduced) was injected at the commissure of the lip and along the line of the pulsating vessels. Ice was applied and the infiltration edema allowed to subside. The lips were kept very tense by an assistant, who also controlled the blood supply. With a fine and very sharp scalpel the mucous surface was carefully incised on one side of the dilated vessel and the edges of the incisions raised with dissecting-forceps. In this way a tortuous and rather thick vessel was brought into view. A blunt hook was then inserted under it and the vessel was soon detached from its loose connective-tissue surroundings. By pulling on the artery its course was easily traced to each commissure and the overlying parts were cut with sharp-pointed scissors. Two collateral ramifications, also dilated, were followed on each side of the frenum and ligated. After removal, the chief artery curled up and contracted to about $1\frac{1}{2}$ cm., or one-half its original size. The vessel walls were unusually thick and were undoubtedly in a state of endarteritis. The incision required for the extirpation was readily closed by a few interrupted catgut stitches. The use of a mild antiseptic mouth wash and a weak peroxid of hydrogen spray was the only after treatment. The wound healed readily and the patient was advised not to play for at least two months. He has since resumed his regular occupation and has played during two winters in succession without experiencing the least inconvenience.

The interest in the case centers in the fact that this was an acquired or pathologic varix, not nevoid,—simply a dilatation of a distinct arterial trunk and a few collateral branches. It probably was associated with the special exercise to which the lip was subjected, and in this way differed essentially from the nevoid and other forms of congenital or acquired angioma which are so frequent in this region.

A CASE OF ACUTE OPIUM POISONING TREATED WITH OXYGEN, VENESECTION, AND HYPODERMOCLYSIS.

SERVICE OF DR. S. S. STRYKER, PRESBYTERIAN HOSPITAL,
PHILADELPHIA.

Reported by ALBERT E. BLACKBURN, M.D., Resident Physician.

W. F., male, forty-four years of age, was admitted to the Presbyterian Hospital June 26, 1897, with a history of having been found at his home in a deep sleep from which it had been impossible to arouse him. A three-ounce bottle, which had contained laudanum, was discovered in his room.

Upon examination the patient was found to be intensely cyanotic and could not be awakened. His pupils were

reduced to a pinpoint in size and did not respond to light. Respirations were reduced in number to nine every five minutes and were labored and stertorous. The breath bore a very strong odor of alcohol and a slight odor of laudanum.

A tube was introduced and the stomach thoroughly washed out with plain water, the first return of the fluid being brown in color and possessing a marked odor of laudanum. The viscus was then washed out a number of times with a 1 to 5000 solution of permanganate of potash, which, in turn, was followed by plain water. Three hypodermic injections of atropin sulphate, one-hundredth of a grain, were given in rapid succession, together with an enema of a strong infusion of coffee. Artificial respiration, the galvanic current, and the application of hot water to the epigastrium—all were tried, and a cone connected with a reservoir of pure oxygen was kept constantly over the nose and mouth. One hundred and forty gallons of the gas was used during the treatment.

Three hours elapsed and the condition of the patient had in nowise improved. It was then suggested that, as considerable absorption of the drug probably had taken place, the blood necessarily was surcharged with laudanum, and if good results were to be obtained this poisoned blood must be removed as far as possible and another circulating medium substituted. Accordingly twenty-five ounces of blood was removed by venesection and one and one-half pints of normal salt solution introduced in its place. As a result of this treatment, the cyanosis gradually disappeared, the pupils dilated and responded to light, and the respirations increased in frequency and became quiet.

The after-treatment was symptomatic. A soft, blowing systolic murmur, which had developed during the efforts made to resuscitate the patient, disappeared after forty-eight hours. It was afterward learned that the man had swallowed two ounces of laudanum two hours before his admission to the hospital.

MEDICAL PROGRESS.

Suture of the Popliteal Artery.—ORLOW (*Centralbl. für Chir.*, May 29, 1897) opened the popliteal artery during an operation, making a wound in it about one-third of an inch long. This was closed by five sutures, three of them passing through the whole thickness of the wall and two of them including merely the adventitia. Three days later, there was distinct pulsation in the arteries of the foot. It became necessary, subsequently, to amputate the limb, and the popliteal artery was found to be pervious, though somewhat narrowed at the point of suture. Orlow found it much easier to suture this artery than to suture those of an animal.

Softening of the Brain Following Ligation of One Internal Jugular Vein.—ROHRBACH (*Beiträge zur Klin. Chir.*, vol. xxvii, p. 811) describes a case in which softening of the brain followed ligation of the left internal jugular vein. A woman, aged fifty-seven, had metastatic nodules of carcinoma in the left side of her neck, which were found

at operation to be so closely attached to the internal jugular vein that the removal of a portion of this vessel was imperative. There was no return of consciousness after the effects of the anesthetic had passed off, but a comatose condition persisted and grew deeper, the reflexes being lost. Death followed six days after the operation. The autopsy showed extensive softening of the brain, due to retention within the cranium of venous blood. An explanation of this condition was found in the small caliber of the right sinus transversus, the lumen of which barely admitted a knitting-needle. Among ninety-one cases of ligation of one internal jugular vein which have been reported, not one presented a disturbance of circulation so serious as that which occurred in this instance. In nine there were transitory symptoms only.

The Microscopic Character of Adenoids.—BRINDEL (*Centralbl. f. Chir.*, May 29, 1897), in an examination of adenoids from sixty-four patients found tuberculosis eight times, although in only one instance did he succeed in staining the bacilli. The other growths which were considered tuberculous contained scattered caseous areas and a few giant cells.

Radical Cure of Perforating Ulcer of the Extremity.—CHIPAULT (*La Presse Méd.*, May 29, 1897) reports seven attempts to cure perforating ulcer of the foot by stretching of the plantar nerves, with only one failure. All of the patients were laborers, and the ulcerations were deep, and in some instances associated with osseous lesions. All were in bad hygienic condition. In every case the nerve was stretched either under the internal malleolus, or external malleolus, or at the border of the Achilles tendon; in a word, at a moderate distance from the trophic ulceration. At the same time that the nerve was stretched, the ulcer was thoroughly curetted, necrotic bone removed, and the thickened edges of the ulcer excised, thus transforming a round infected ulceration into an oval wound, whose edges were sutured together. In this manner the most obstinate cases may be successfully treated.

THERAPEUTIC NOTES.

Bromoform in Whooping Cough.—HOGE (*Virginia Med. Semi-Monthly*, May 28, 1897) has tested the value of bromoform in whooping cough in a number of cases, and concludes as to its therapeutic value, that it has absolutely no good effect in lessening the paroxysms or cutting short the disease. As to its dosage, he concludes that it should never be given on an empty stomach, and not at all to children under two months of age. For a child one year old, six drops four times daily is safe.

Medical Treatment of Pyelitis.—ROBIN (*Bull. Gen. de Thérapeutique*, April 30, 1897) advocates medicinal treatment of pyelitis, at least up to a certain stage. Attention should be directed toward the diet and hygiene, while of medicines, the balsams, revulsives, and especially mineral waters, are able to exert a favorable influence upon the disease. Every effort should be made to excite

the secretory action of the skin. The diet should be exclusively of milk if the patient is able to endure it. Of medicines, benzoic acid, or its less irritable salt, benzoate of soda, is the most valuable. It may be given in the following prescription:

℞ Benzoate of soda . . .	gr. xv-lx
Cherry laurel water . . .	℥ iv
Syr. of orange flowers . . .	℥ i.

To be taken in four doses during a period of twenty-four hours.

Under the influence of this medicine, there will be in the first few days a discharge of alkaline urates, which may possibly provoke renal colic. In conjunction with the benzoate of soda, balsams, like those of tolu, copaiba, styrax, turpentine, etc., may be employed. After this treatment has been continued for a few days there may be given in place of it, Haarlem oil, a preparation which contains, among other things, oil of cade, and laurel.

If acute symptoms manifest themselves, revulsive treatment in the form of slight cauterizations with the paquelin point, perhaps as many as seventy or eighty upon the affected side, will be found useful. Astringents, such as gallic acid, tannin, or above all, iodo-tannic syrups, are needed to counteract the relaxation occurring in this tedious disease. The mineral waters selected must not be those producing alkalinity of the urine. Moreover, they should be light in action and easily borne and digested. In long standing cases, chalybeate waters act favorably.

Constipation in Babies.—For constipation occurring in babies during the first year and not relieved by a regulation of the diet, CARRON DE LA CARRIERE recommends, in the *Revue de Therapeutique*, May 1, 1897, a light massage of the abdomen with the palm of the hand well oiled. The movement should be made in a circle about the umbilicus, pressure being light and exerted especially in the right iliac region. Each seance should occupy not more than ten minutes, and should take place in the morning. For babies after the first year, massage may be given with the finger tips over the course of the large intestine from right to left.

For Eczema Ani.—

℞ Powdered camphor . . .	2 parts
Zinc oxid . . .	} aa . . . 30 parts
Bismuth subnitrate . . .	
Talcum . . .	40 parts.

M. Sig. Apply after each movement, first washing the parts with boracic-acid solution.—*Ther. Wochenschr.*

Treatment of Nephritis by the External Use of Pilocarpin.—

JULIA (*Gaz. heb. de Med. et de Chir.*, June 27, 1897) gives the following directions for the use externally of pilocarpin in cases of nephritis:

℞ Pilocarpin nitrate . . .	gr. i
White vaselin . . .	℥ ii.

This ointment is rubbed upon the lumbar region and covered with cotton and oiled silk. If the perspiration is very profuse, the ointment may be removed after two hours, but it is better to leave it longer if possible.

The action of the drug applied in this way is surer, more rapid, and less dangerous than when given internally.

Hair Tonics.—These two "hair tonics" have much to recommend them, the first for its lack of alkalinity and bleaching tendency, the second for its combination of oil with alcohol.

(1)	
℞ Quin. sulph.	gr. xx
Ac. sulph., dil., ...	q. s.
Tinct. canthar.	℥ i
Hazelin	℥ ii
Glycerin	℥ i
Aq. Flor. aurant. q. s. ad	℥ viii.

(2)	
℞ Tinct. canthar.	℥ xiv
Tinct. cinchon.	℥ ii
Tinct. benzoin	℥ vi
Spts. lavand.	℥ iss
Ol. ricini	℥ ii
Alcohol q. s. ad	℥ x.

Dissolve oil in alcohol, and add other ingredients.

After a vigorous application, all excess should be dried off with a towel.—*Jour. Cut. and Gen.-Urin. Dis.*

Aristol in Operations upon the Nose.—COX (*Brooklyn Med. Jour.*) says that there is no better remedy for use in the nose after operations than aristol, which "adheres closely to abraded surfaces, when insufflated, acting as a protective and cicatrizing, deodorizing most effectually without substituting any odor of its own." It is especially valuable as a dressing after operations for hypertrophy of the turbinated bones, abnormalities of the nasal septum, removal of polypi, etc.

ANDERSON (*N. Y. Med. Jour.*) states that when insufflated upon cut surfaces aristol acts not only as an antiseptic, but adheres firmly and prevents the constant oozing of blood and serum from the wound. Furthermore, it reduces to a minimum any reaction occurring as a result of the operation.

The Relief of Confirmed Insomnia.—BROWNE (*Lancet*, May, 1897) states that even in cases of confirmed insomnia, which have been treated unsuccessfully by means of chloral, paraldehyde, and other hypnotics, each drug in turn having to be increased in dose until it finally loses all power or becomes dangerous, trional, in his hands, has afforded marked relief without apparent ill effect, and has given tranquil, refreshing sleep without any increase of the initial dose. One of the author's patients, a retired surgeon, a museum of complaints, having mitral insufficiency, gout, eczema, albuminuria, and marked emphysema, who had tried every known hypnotic for obstinate insomnia, has been taking 15 to 20 grains of trional during the last five months, almost every night. He has never had to increase the dose, his heart has been much benefited by the regular sleep, and his nocturnal attacks of dyspnea are now unknown. It is the author's custom to administer an initial dose of 20 to 24 grains, which usually may be reduced to 15 grains or less, and when given in this way he has found it invaluable for breaking a pernicious habit of sleeplessness where a few good refreshing nights may restore the normal habit of sleep.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

Address the Editor: J. RIDDLE GOFFE, M.D.,
NO. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM IN ADVANCE	\$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

AND NOS. 706, 708 & 710 SANSON ST., PHILADELPHIA.

SATURDAY, AUGUST 14, 1897.

AN ABUSE DEMANDING THE ATTENTION OF THE BOARD OF HEALTH.

It is a notorious fact that there has developed in this city during the past year or two a series of low liquor dives whose nefarious practices involve a serious question of health. These dives are known vulgarly among the more aristocratic saloon-keepers as "morgues"—not *post-mortem*, but *ante-mortem*, morgues—for it is here that the fatal spirits are dispensed. It is currently reported that there are hundreds of such places in New York, where alcohol diluted with water and glycerin and other fatal concoctions are sold as pure spirits. As might be expected, these places are in poor neighborhoods in the densely populated parts of the city, and are patronized by depraved, needy, and dissipated persons of both sexes. Such patrons no longer get the expected response from an ordinary cocktail, and demand something of a more fiery nature and at a reduced rate. These morgues are, as their name implies, dismal places, from which all inducements to conviviality are excluded, and in which, therefore, the patron is not expected to tarry. One drink of the hot and venomous stuff is quite enough.

This is thrown down with a gulp, the requisite five cents is deposited, and the unthinking victim goes on his or her way in nervous haste or with languid step, as the case may be.

The moral influence of such an institution is not the point to which we wish to call attention, for that naturally comes more within the sphere of the police department or of the Church, but as sources of physical degeneration they invite the attention of the profession and more especially of the sanitary authorities.

Commercially, such places bear about the same relation to the legalized saloon that the bucket-shop bears to the Stock Exchange. They might justly be called the bucket-shops of the liquor trade, and, indeed, they have extended their business to such an extent as to attract the attention of the Wine and Liquor-Dealers' Association. The efforts of the Stock Exchange to suppress bucket-shops are inspired partially by the desire to overcome opposition and indirectly by a moral sense which aims to rescue the great mass of unthinking humanity, the newsboy, the messenger-boy, the bookkeeper, and the low-salaried clerk from the temptation to squander their small savings in an investment in which all the chances are against them. In the same way the Liquor-Dealers' Association, in its efforts to overcome the business competition of these morgues, is at the same time rescuing this low class of society from certain physical wreck and death. In this way, sometimes, the workings of natural and commercial laws will right many abuses, but in this instance it would seem that there is a legitimate field for the intervention of the Board of Health. If these *ante-mortem* morgues could pass on their victims direct to the *post-mortem* morgue, their influence upon the community might be considered beneficial rather than baneful, but the workings of the nefarious business is to fill the wards of the City's hospitals with patients suffering from gastritis, enteritis, cirrhosis of the liver, and a long train of inevitable complications, to be treated and nursed back into sufficient health to enable them to repeat their round of visits to the five-cent counters, and again appear in the hospital wards.

The Babies of Paris.—It is said that 18,000 out of the total number of children annually born in Paris are inevitably put out to nurse.

CANCER OF THE RECTUM.

IN a paper on this subject, read by James P. Tuttle of New York before the Chicago Academy of Medicine, January 8, 1897, the following facts are made clear: Of 487 excisions of the rectum for cancer, done before 1885 by the perineal method, 22.4 per cent. died from operation; of 512 cases done by the sacral method from 1885 to 1892, 20 per cent. died from the operation; while of 257 cases operated upon since 1892, most of them by the sacral method, 11.5 per cent. died from operation. The mortality for the future may, therefore, be counted as less than 10 per cent. It is less than this for the perineal operation and somewhat more for the sacral one. The former should, therefore, be chosen in all cases in which the disease is located sufficiently low down to permit of thorough and complete removal.

With regard to prognosis, nearly 10 per cent. of the 219 cases operated upon which could be traced, have passed three years without recurrence. As recurrence after that period of time is very rare, these patients may be regarded as cured. About 70 per cent. of the remainder have as yet had no recurrence in periods varying from a few weeks to over two years.

The outlook with reference to prolonged life is even more satisfactory. In the 219 cases traced, the average duration of life was, up to the time of report, two years and three months. As 181 of them were still alive it is evident that the average duration of life after the radical operation is considerably greater than this; and what is still more important, these patients are all sustained and cheered by the hope of cure until recurrence actually appears. The average duration of life without operation is about one year. After colotomy, even if the life is prolonged—a claim not yet made good by statistics—the patient has absolutely no hope of escaping the disease.

The most frequent cause of death after operation is shock, and the second in order, septic peritonitis. These two causes accounted for 17 out of the 31 deaths. The others were due to anemia, 3; iodoform poisoning, 2; exhaustion, 2; hemorrhage, 1; empyema, 1; cerebral complication, 2; unknown, 2; and suppression of urine, 1.

The lack of fecal control which must evidently follow if the sphincter is removed, may be avoided, at least temporarily, by Gersung's plan of twisting

the rectum before suturing it, or by bringing the rectum through between the fibers of the gluteal muscle—a method advocated by Jaennell and Willems.

As a palliative measure, excision is far more successful and beneficent than any other means of treatment. The writer can see no good grounds either in theory or practice for performing a preliminary colotomy. In order to avoid sepsis, he emphasizes the rule, "during operation keep your fingers out of the rectum, and do not open it until the peritoneum is closed."

This elaborate article must have required years of careful search and investigation into the literature of the subject, and is another indication of the amount of valuable information each specialty has in store for one who investigates it thoroughly.

ECHOES AND NEWS.

Lockjaw from a Gun-shot Wound.—A man recently died at Trenton, N. J., from lockjaw as a result of a gun-shot wound, accidentally received while out gunning.

The Oldest Doctor.—The oldest physician in the United States is Dr. Stephen Adams, aged ninety-four, who lives in West Newfield, Mass. He was graduated in 1828.

Lord Wolseley Has Cancer.—The report comes from London that Lord Wolseley, Commander-in-Chief of the British Army, is suffering from cancer of the throat, due, it is said, to excessive smoking.

Fatal "Mushrooms."—The family of a man living at Rockford, Ill., recently ate of what were supposed to be mushrooms. As a consequence one child is already dead and another is not expected to survive.

Lizards in His Stomach.—A young farmer of Lancaster, Pa., who has been ailing for some months, recently vomited up twenty-four lizards, many of them over three inches long, and a number of lizard eggs.

The Prince of Wales and the Medical Profession.—The Prince of Wales was unanimously elected an Honorary Fellow of the Royal College of Physicians of London at a recent meeting. He is the only Honorary Fellow of that institution.

The Foulard Library.—The library at the St. Louis Hospital, Paris, founded by Dr. Foulard, who perished in the Charity Bazaar fire, is to be named after him, and a subscription has been opened to collect funds to erect a bust to his memory.

Work of Female Convicts.—In England convicts are not allowed to become crazy from lack of employment. It is said that the female convicts of Woking prison did all the mosaic work with which the crypt of St. Paul's cathedral is paved.

Pure Water and Reduced Death-Rate.—It is said that there has been a great reduction in the death-rate from typhoid fever in Jersey City since the polluted water of the Passaic river has been exchanged for the pure water of the Highlands of New Jersey.

Death-rate in Model Dwellings.—According to the *London Chronicle*, the death-rate in the model dwellings put up by the Metropolitan Association for Improving the Condition of the Working Classes is only 9.64 in 1000—half the rate for the whole of London.

Dismissed the Staff.—A misunderstanding between two of the consulting physicians of the Bayonne (N. J.) Hospital and Dispensary has resulted in the dismissal of the entire staff. It is probable that the Board of Managers will re-appoint the members of the staff with one exception.

In Bed Thirty-Nine Years.—There recently died in England a woman aged seventy-seven years who had spent the last thirty-nine years of her life in bed, although perfectly well in every respect. She simply made up her mind that a bed was the most comfortable place in the world, and stayed there.

A Baby-Detective.—This is the name given to a young woman who is employed by one of the hospitals of New York City to "run down" the parents of sick babies which are left in that institution. The "baby-detective" became necessary, because many parents deserted their children after placing them in the hospital.

Suicide of Russian Doctors.—According to the *Lancet*, the many free and heavily endowed dispensaries in Russia are responsible for a large percentage of the many suicides among physicians of that country. Doctor's fees are generally very low in Russia, 20 kopeks (6 cents) being a not uncommon charge for an office consultation.

New Fireproof Building for a Pathologic Museum.—At the urgent request of Professor Virchow, a new fireproof building is about to be erected for the collections of the pathological institute of the Berlin Institute. These celebrated collections, containing many rare specimens, are now stored in a building which offers no protection against fire.

A Homeopathic Pharmacopœia for Germany.—The news comes from Berlin that a homeopathic pharmacopœia, which is to be officially recognized, is in course of preparation in Germany. The superintending committee, composed of homeopathic doctors, dispensing chemists, and a few university professors, held its first meeting August 11, 1897.

Asleep for Three Months.—Nebraska has a sleeping boy. He is fourteen years old and has always required more sleep than most boys of his age, often spending sixteen or eighteen hours in bed. For the last three months he has remained in bed altogether, during which time he has barely opened his eyes half a dozen times. Food in liquid form is forced into his mouth and swallowed.

Death of Dr. J. J. Curran.—Dr. John Joseph Curran of New York died on the 24th ult. of heart failure. His

brother, Dr. F. W. Curran, was lying dangerously ill in the same house and was not told of his death. The burial took place on the thirty-seventh anniversary of Dr. Curran's birth. He was a graduate of the College of Physicians and Surgeons of New York.

Patent-Medicine Man Fined.—Lord Nelson's old battleship, "Foudroyant," was fitted out not long ago as a Nelson museum and exhibitions given at various English seaports. An enterprising patent-medicine man one night caused to be painted on her side an advertisement recommending a certain kind of pill. At the Liverpool assizes he was fined \$260 for defacing the old battleship.

Italian Foundling Hospitals.—The appalling revelations of the mortality in these institutions have led to the nomination of a committee of inquiry into the whole subject—the illegitimacy which gives rise to the system of foundling hospitals, the provocatives of that illegitimacy, and the administration of the hospitals. The committee is composed of high medical authorities, members of Parliament, and other well known men.

A Medical Saint.—Of the two new saints recently added to the calendar by the Pope, it is interesting to note that one was a member of the medical profession—Saint Antonio Maria Zacaria, who was born in Cremona in 1503. Among other medical saints in the Roman calendar besides St. Luke, the "beloved physician," are two others, Saint Cosmos and Saint Damian. The old College of Surgeons (Saint-Côme) in Paris was named after the former.

Sanatorium Patients Injured.—Fifteen patients of the Loomis Sanatorium for Consumptives at Liberty, N. Y., were badly injured, some fatally, in a runaway accident recently. While descending a steep hill, one of the whiffletrees broke and frightened the horses, which dashed down the incline and overturned the wagon, throwing the occupants violently on the hard roadbed. Several of the least injured members of the party were seized with hemorrhage immediately after being picked up.

Rabies in American Dogs.—The recent order of the Board of Agriculture of Great Britain directed against the importation of American dogs into England, together with the numerous sensational newspaper articles on rabies which have appeared, has led the American Kennel Club to appoint a committee to investigate and report upon the existence of rabies in America. The various lines of investigation of the prevalence of this disease which have been instituted will eventually afford reliable data of positive information.

Death of Dr. John Love.—Dr. John Love of Montclair, N. J., died of heart disease on July 30th. His death was unexpected for he had not been ill. He was suddenly stricken just after completing a surgical operation and expired immediately. Dr. Love was born in Warren County, N. J., in 1833, studied in a private school and was graduated from Lafayette College, Easton, Pa., and the Medical Department of the University of New York. He entered the United States Army in 1862, and in 1863

was a brigade surgeon-in-chief in the Army of the Potomac.

Death of a Whale from a Curious Cause.—A white whale was recently brought to the New York Aquarium from Canadian waters, and died soon after from edema of the lungs, due to a strange accident. As is well known, a whale is obliged to come to the surface every ten or twenty minutes in order to blow and is provided with a blow-hole in which there is a valve which opens and closes as rapidly as the whale exhales impure and inhales pure air. An eel became lodged in this blow-hole and, despite the efforts of the whale to dislodge it, it held open the valve in such a manner that the water rushed in and filled the lungs, thus drowning the whale.

Death of Sir John Charles Bucknill, M.D., F.R.S.—The death on July 20th is announced of Sir John Charles Bucknill. He was born in 1817. In 1840 he took the degree of M.D. in the University of London with honors in surgery and medicine, and in 1844 was appointed the first medical superintendent of the Devon County Lunatic Asylum. Subsequently, he devoted himself to the study of mental diseases. He was one of the founders of the *Journal of Mental Science*, which he edited for many years. He was a voluminous writer. He became a fellow of the Royal College of Physicians of London, and in 1877 delivered the Lumleian lectures.

Pasteur Memorial.—The medallion, which was voted by the Municipal Council of Paris for the purpose of commemorating Pasteur's work, has been placed on the outer wall of the École Normal Supérieure. The medallion is of bronze with a gilded background. A rose-colored oak and laurel wreath surrounds it, the whole being placed on a black marble slab, which bears the following inscription:

"HERE WAS PASTEUR'S LABORATORY.

- 1857. Fermentations.
- 1860. Spontaneous Generation.
- 1865. Studies of Wines and Beers.
- 1868. Silkworm Diseases.
- 1881. Virus and Vaccines.
- 1885. The Prophylaxis of Rabies."

The International Congress at Moscow.—The reception of deputations by the Czar will be held August 17th (August 5th in Russia) in St. Petersburg. The deputation will consist of one representative from each country, the choice of representatives being left to the national committees of the different countries. The presentations will be made by Professor Skifosovski, the president of the Organizing Committee of the congress. The interest of the court in the congress is further shown by the offer of the Ministry of the Court to accommodate twenty-three members in the Maison des Cavaliers, one of the official residences in the Kremlin, where they will be treated in all respects as guests of the court.

Study of American Medicinal Flora.—The Pan-American Medical Congress, at its meeting held in the City of Mexico in November, 1896, took steps to institute a systematic study of the American medicinal flora through the me-

dium of a general commission and of special sub-commissions, the latter to be organized in the several countries. The sub-commission for the United States has been formed and has entered into an association with the Smithsonian Institution for the purpose of studying the medicinal plants of this country. This committee solicits information concerning the medicinal plants of the United States from everyone in position to afford it. All packages and correspondence on this subject should be addressed to the Smithsonian Institution, Washington, D. C., and marked on the outside, "Medical Plants for the United States National Museum." Franks which will carry specimens, together with descriptions and notes, free of postage through the mails, will be forwarded upon application. For further information address the Smithsonian Institution, Washington, D. C.

The Army Medical Board.—This board will be in session at Washington, D. C., during October, 1897, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the board will make application to the Secretary of War before September 1, 1897, for the necessary invitation, giving the date and place of birth, the place of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning November 1, 1897. Further information regarding the examinations may be obtained by addressing Geo. M. Sternberg, Surgeon-General, United States Army, Washington, D. C.

CORRESPONDENCE.

DEATH FROM DRINKING COAL-OIL.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: A report of the following unusual case may prove of interest:

On June 26, 1897, I was hurriedly summoned to attend a child, fifteen months of age, who, two hours previously, had drunk about four ounces of coal-oil. Immediately after the ingestion of the oil the patient had been given castor-oil, sweet milk, and vinegar, and then salt and water, which produced slight vomiting.

Upon my arrival I found the child unconscious, breathing heavily, and almost pulseless. Its skin was cadaveric in hue, pupils slightly dilated, and the lips, tongue, and throat swollen and blistered. I administered a small quantity of a saturated solution of alum as an emetic,

but as it was unproductive of results, I resorted to the use of stimulants and external heat. The patient died four hours after the accident occurred. An autopsy was not permitted.

I have been unable to find a report of a case similar to this, although in the United States Dispensary is contained an account of a man, who, after drinking petroleum, was saved by the prompt exhibition of emetics. I would like to know if there is any drug which will act as an antidote under these circumstances, and, in the treatment pursued in this instance, if the administration of the castor-oil and milk served to emulsify the coal-oil and thus hasten its absorption.

W. C. HAMILTON, M.D.

STEWARTSVILLE, MO., JULY 31, 1897.

UMBILICAL ASEPSIS IN THE NEWBORN.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: My attention recently has been directed to this subject by an article by Samuel W. Lambert, M.D., entitled "Umbilical Sepsis in the Newborn, Occurring at the Nursery and Child's Hospital, New York, During 1896," published in THE MEDICAL NEWS, May 1, 1897.

Applying the rules of general surgery, since 1893 I have eliminated after-treatment of the umbilical cord from my obstetric practice by amputating the cord at the umbilicus. After applying two artery forceps and severing the cord between them, the child is handed to the nurse. After completion of the third stage of labor, and after the necessary attention has been given to the mother, including suture of the perineum, if it has been lacerated, I return to the cord. My hands previously having been prepared, the field of operation is rendered sterile, the hemostatic forceps are moved up to the junction of the cord and the skin, the cord is severed close to the forceps, and the vessels picked up and separately ligated with small-sized catgut. Subgallate of bismuth and aseptic gauze are then applied and held in place by a cheese-cloth bandage. The wound heals under a scab, and is safe from infection.

In my next case I shall take a step forward by suturing the wound and sealing it with collodion. I will not claim originality for this method, for, although it is original so far as I know, I have not made an exhaustive study of the literature on the subject. I wish to suggest the general adoption of this as the best method of treating the cord, and would like to learn of any objection to its employment.

CHAS. E. B. FLAGG, M.D.,

Assistant-Surgeon, U. S. A.

FORT DUCHESNE, UTAH, July 20, 1897.

TAKING THE MEDICAL PROFESSION INTO PARTNERSHIP.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: The ways of the commercial physician are many and devious. The other day I came across a new one—or perhaps it is not new—in which you may be interested. A friend asked my opinion as to the advisability of presenting for censure to the County Medical Society the writer of a letter which he had received, and

the addressing of which to him he considered an insult. The question answered itself when we found that the letter-writer was not a member of the County Society. I append for the delectation of your readers some extracts from the letter:

"....."

"..... street,

"Philadelphia, Pa.

"....., A.M., M.D.,

"Editor and Publisher.

"..... 27th, 1897.

"DEAR DOCTOR: The Water Co. has placed in our hands a block of their capital stock for free distribution among the physicians of this city. The par value of each share is \$100, and the stock is full paid and *non-assessable*. The company is *now* doing a good business, and its stock is sure to become a very profitable investment. I have personally investigated visited the springs and . . . used the water, and I can say emphatically that it is as good as any water on the market. . . . There is *nothing to pay* for the stock; only investigate the merits of the water and, if satisfied, agree to recommend its use. The block allotted to Philadelphia is not large; and from present indications will be quickly disposed of, so that we must know soon who want it. I enclose a pamphlet that was prepared for circulation among the laity only. . . . This is, I believe, the only form of advertising which the company has yet employed. I am permitted to use my discretion in the distribution of the shares, and I will be pleased to have you refer to me any of your personal medical friends who might be glad of the opportunity to secure some of this stock. . . ."

What do you think of it all, anyhow?

Yours very truly,

SOLOMON SOLIS-COHEN.

PHILADELPHIA, July 20, 1897.

OUR VIENNA LETTER.

[From our Special Correspondent.]

PROFESSOR KARL TOLDT, THE ANATOMIST, AS RECTOR OF THE UNIVERSITY—THE FIRST WOMAN DOCTOR IN HUNGARY—AVAILABILITY OF LATENT NERVE FORCE AFTER INJURY AND DISEASE, WITH AN EXPERIMENTAL DEMONSTRATION—OSTEOPHYTOSIS IN THE PELVIS IN CASES OF ECLAMPSIA.

VIENNA, July 24, 1897.

DR. KARL TOLDT, Professor of Anatomy in the Medical Department of the University, has been selected as Rector magnificus of the Imperial Royal University during the scholastic year of 1897-98. He succeeds Professor Leo Reinisch of the Faculty of Philosophy, and the selection seems to be a source of very general satisfaction. The office is almost entirely an honorary one, and does not include what to our American ideas constitutes the main duties and responsibilities of the head of a university faculty. Financial matters, and all questions of modification of policy and establishment of new chairs and departments practically are in the hands of the Government.

Thus the yearly tenure of office is not beset with the difficulties it would have with us.

Hungary has not allowed herself to be long distanced by her sister kingdom, Austria, in the matter of conferring degrees upon women. The promotion to the doctorate in medicine, at Buda-Pest, of Countess Vilma Hugonay was recently announced. She is the wife of Dr. Vincent Wartha, the Rector of the Hungarian Polytechnic Institute in Buda-Pest, and has made her medical studies at various places in Germany and finally, like the Baroness Posanauer, the first woman promoted to the doctorate in Austria, at Zurich, Switzerland. This promotion, it is understood, will open up the Hungarian universities to women, as did the corresponding procedure here in Austria, and it is welcomed very enthusiastically by friends of the higher education of women.

A series of experiments performed after the removal of the cortical motor centers of an ape, which were recently carried out by Assistant-professor Biedl for Professor Stricker's lectures on Experimental Nervous Pathology, gave some interesting and unlooked-for results. Before operation the animal would always stretch out its right paw to grasp any dainty extended to it. After what was thought to be complete removal of the corresponding cortical center, and recovery from the shock of the operation, the left paw was always extended. During an interval of some weeks, while the animal seemed perfectly well otherwise, the right paw hung limp and motionless, and seemingly was without power. Then the cortical centers in the other hemisphere were excised. To the surprise of the experimenters after recovery from the operation the animal immediately began to use its right paw almost as well as before the first operation. There had been some awkwardness noticed after the first operation, seemingly until proper control of the left paw could be obtained by exercise, but after the second operation the right paw at once resumed all its old functions.

Autopsy showed that while it had been the intention at the first operation to remove the whole of the cortical area corresponding to the right paw, this purpose had not been accomplished and some of the peripheral parts of the area remained. The injury was sufficient to temporarily paralyze the motor paths to the right paw, and to make it more convenient for the animal to acquire by exercise more control of the motor paths on the other side, but as soon as this was interrupted by thorough removal of the corresponding cortical areas of the left side the use of the right paw was resumed.

The observations are of interest as showing how natural powers, when somewhat weakened by injury, faulty development, or pathologic process, may be held in complete abeyance, unless called forth by some special natural necessity or careful training. The experiments illustrate the principle that underlies certain lines of treatment for nervous affections which are just being developed, and should be a source of encouragement to the clinician studying such methods. The treatment of tabes by regulated exercise, and the teaching of coordinated movements, is a striking example of this bringing into play of nerve forces seemingly entirely destroyed by disease but

in reality only in abeyance because properly directed and persistent effort is not made to use them. Another such state of affairs is found in some of the spastic palsies of children in which American orthopedic surgeons, notably De Forest Willard, have accomplished much by properly setting the children on their feet, supporting them with suitable apparatus when necessary, and encouraging them in the effort to walk.

A striking example of this availability of nerve force, which under ordinary circumstances is latent, can be seen here in Vienna, in some of Professor Urbantschitsch's successes with deaf mutes. A certain number of congenital deaf mutes, by a series of regulated exercises in hearing, are brought to appreciate sounds which were completely beyond the range of their hearing at the beginning of the treatment. People with lessened hearing from nerve injury or disease in later life are often strikingly improved by practice. The whole subject of bringing out the capabilities of nerve force is an old and familiar one, being nothing more than the practice which is always indulged in when a complicated action is to be performed readily and easily, but this application of it to weakened nerves is only just being appreciated. Some experiments made with Parkinson's disease, and with senile tremors, show that these may be influenced in this way, and the further application of methodical exercises to certain other forms of nervous disease which run a slow course seems but a question of time.

An interesting case turned up in the autopsy-room the other day, which illustrates very well the completeness of the *post-mortem* section methods in Vienna. Death was due to pneumonia, but during the course of the autopsy a section of the liver showed the presence of remains of hemorrhages into the liver substance such as occur in poisoning from certain fungi, such as poisonous mushrooms, etc., and have recently been noted as occurring in eclamptic cases. In this case the bony pelvis was at once removed for examination. When cleared of all soft tissues it was found to weigh nearly three times as much as the normal pelvis under such circumstances, though the subject was only of medium size and development. After maceration, the increased weight could be seen to be due to hypertrophy of the bony structure, not leading to pelvic deformity, but filling up the interstices of the spongy, middle layer of bone and decreasing its translucency. It has long been a subject of general observation that osteophytes in the skull are found in many, even in most cases of eclampsia, but their occurrence in other bones has not been noticed so frequently. Here, however, they are found in nearly all cases to a greater or less degree and sometimes, as in this instance, are discovered when the clinical history says nothing of eclampsia, but where the irritant action of the eclamptic toxins has written the history of its presence in indelible signs in the bony skeleton of the patient. Whether some such bony changes will now be found in cases of mushroom poisoning, which possess certain similarities to eclampsia in the other *post-mortem* findings, is an interesting question. As the process usually is an extremely acute one it may be that they will not be demonstrable.

ACUTE ASCENDING PARALYSIS OCCURRING DURING TREATMENT FOR RABIES—BILATERAL RESECTION OF THE LARGE CERVICAL SYMPATHETIC NERVE FOR EXOPHTHALMIC GOITER—ANEURISM OF THE AORTA MUCH IMPROVED BY INJECTIONS OF GELATIN—MULTIPLE PNEUMOCOCCIC SYNOVITIS—GASTRIC DILATATION IN INFANTS—SIMULTANEOUS OCCURRENCE OF TUBERCULOUS MENINGITIS AND TYPHOID FEVER—ETHER IN UREMIC DYSPNEA—A SUPERNUMERARY URETER.

AT the session of the Academy of Medicine, held June 15th, RENDU described *an acute ascending paralysis occurring during antirabic treatment*. On March 19th, last, a man entered the Necker Hospital suffering from hydrophobia, and died the same evening. The following day, at autopsy, a boy employed in the institution pricked his finger. The wound was treated antiseptically and gave no evidence of inflammation; nevertheless, at the advice of friends, he went to the Pasteur Institute for a course of treatment. From March 22d to April 1st he received sixteen injections of about forty-five minims each. On the 11th day of treatment he experienced a slight chill and a general feeling of fatigue; on the following day, there was painful tingling in the legs, with numbness, lumbago, and fever. On the thirteenth day he awoke with almost complete paraplegia, with anesthesia, from the umbilicus downward. It was still possible for him to pass urine voluntarily but in the evening of the same day this power also was lost. On the fourteenth day the thoracic region began to be affected, and on the fifteenth the arms were the seat of the same symptoms which had at first attacked the legs. On the sixteenth day the heart-beat was much increased and with it appeared a feeling of dyspnea and thoracic pain. The zone of anesthesia was now up to the nipples, and the movements of the head were beginning to be affected. This marked the climax of the paralysis, the ascension of which occupied six days. After nineteen days all of the marked symptoms had disappeared, but the convalescence extended over a period of six weeks.

The question arose whether this paralysis might not have been due to hydrophobia. This hypothesis was rejected for several reasons: First, its onset was too sudden; fourteen or fifteen days is regarded as the minimum of the period of incubation. In this case, however, on the eleventh day there were marked symptoms. Second, the character of the symptoms and the course of the disease did not correspond to those of rabies. Third, death almost invariably follows rabies of a paralytic type. On the other hand, the analogy existing between this case of paralysis and those acute ascending paralyzes of toxic or infectious origin is very close indeed. An objection to this theory lies in the fact that recovery began while the injections still were being given. Rendu, therefore, is of the opinion that the patient reacted with unusual sensitiveness to the introduction of a toxin which for most people possesses no virulent properties.

ROUX called attention to the fact that of 19,000 per-

sons who have received antirabic treatment at the Pasteur Institute, only two have developed paraplegia, that is, one case in about 10,000. Further, no one has been able to produce paraplegia in rabbits by the injection even of very large doses of the antirabic toxins.

GRANCHER regarded the case described as one of hysterical paralysis.

At the session of June 22d, LAMCEREAUX presented a patient, aged forty-six, who for two years had suffered from *an aneurism of the transverse portion of the arch of the aorta*. It was constantly growing and perforation was feared. On January 20th, 1 $\frac{3}{4}$ ounces of a solution containing one per cent. of gelatin and .1 per cent. of chlorid of sodium were injected subcutaneously in the left buttock. This caused a local redness and a temperature of 100.5° F. On the following day the tumor was slightly smaller and more solid. An injection of five ounces was made three weeks after the first one without local or constitutional disturbance. Afterward, twelve similar injections were made, with the result that the tumor became hard and small, while expansile pulsation disappeared entirely.

At the session of June 29th, GERARD-MARCHANT showed a patient upon whom *both the cervical sympathetic nerves had been resected for exophthalmic goiter*. The operation was performed about one year after the onset of symptoms, and the nerve on each side was dissected until its attachment to the large superior cervical ganglion was evident in order to be certain of its identity. About two inches of the nerve on each side was removed. The immediate result of operation was excellent. Four days afterward, exophthalmia, goiter, and tachycardia had all disappeared. Unfortunately this result was not permanent, and in a short time the exophthalmos, which had been the principal symptom, in part returned.

At the session of the Medical Society of the Hospitals, held June 11th, WIDAL and MERCIER mentioned *a case of multiple synovitis occurring in a man after an attack of pneumonia*. It developed successively in the right tibiotarsal articulation, in the sheath of the peroneal tendons, in the prepatellar bursa, in the right shoulder-joint, and finally in the sheaths of the extensor tendons of the right forearm. Pus drawn during life contained an almost pure culture of the pneumococcus. At autopsy, the synovial membranes showed only superficial alteration, consisting in desquamation of the endothelial cells, vascular congestion, hemorrhagic foci, and infiltration with leucocytes. Cases of generalized synovitis following pneumonia are rare, and this instance is worth recording.

At the session of June 18th, COMBY, who has measured at autopsy the stomachs of eighty infants, found dilatation to be present in eighty per cent. The retention of nourishment leads to abnormal fermentation, to putrefaction, and finally to an actual poisoning. To combat this auto-intoxication, it is necessary to modify the diet, and, finally, if this does not suffice, to have recourse to lavage of the stomach, which is very well tolerated by infants and is easily performed.

CHANTEMESSE mentioned a case of *tuberculous meningitis in which the serum taken on several occasions showed agglutinating reaction*. At autopsy there was

found a well-marked tuberculosis of the meninges and lung, while in the intestine Peyer's plaques were ulcerated and contained Eberth's bacilli. This patient was attacked by tuberculous meningitis and at the same time by typhoid fever. The symptoms of the former obscured those of the latter.

At the session of June 25th, LEMOINE reported the result of investigations to determine whether *the virulence of Löffler's bacillus corresponds with the clinical picture of the patient from whom it is obtained.* This query is answered in the main in the negative. Thus, in three cases of severe diphtheria, the bacillus showed itself possessed of a limited degree of virulence, while streptococci and coli bacilli from the same throat possessed considerable virulence. In order to determine the proper time for therapeutic intervention it is thus necessary to rely upon clinical observation in cases of sore throat. Bacteriology can do no more than indicate the mode of intervention. It is only in light and doubtful cases in which bacteriologic examination is necessary.

At the Biological Society, June 12th, LEMOINE and GALLOIS mentioned the success which follows *treatment of uremic dyspnea with large doses of ether* in case the kidneys are not absolutely destroyed. Thus in the uremia of acute nephritis, of renal congestion, either acute or occurring in the course of chronic nephritis, or infectious nephritis, treatment by ether gives the best chance of recovery. Uremia due to a slow disorganization of the kidney by arteriosclerosis is the only form which does not yield to this treatment. Every half hour or hour, according to the case, two or three teaspoonfuls of ether should be given in a little sweetened water. It is better still if every third dose is given subcutaneously, one half of a teaspoonful being sufficient when employed in this way. Some patients take with advantage as much as ten ounces of ether without the least inconvenience and without any symptoms of intoxication. The drug produces in these cases an abundant diuresis, relieves the pulse, and calms the respiratory spasms.

At the session of the Surgical Society of June 16th, ALBARRAN reported a case of *supernumerary ureter opening into the vagina and vulva.* The patient was a girl of twenty years, who had been troubled since birth with incontinence of urine, although she passed water at intervals by the urethra just as a normal person does. Examination showed the presence of several small openings posterior to the meatus both inside and outside of the hymen, from which urine trickled continuously. Cystoscopic examination showed the openings in the bladder of two ureters, and the passage of a fine bougie for eight inches into the vaginal fistula showed that there was no connection with the bladder. The urine passed by the fistula was found upon examination to contain a diminished quantity of chlorids, phosphates, and urea, as compared with the vesical urine, thus showing it to come from a hydronephrotic kidney. An attempt to transplant this supernumerary ureter into the bladder failed on account of the giving way of some of the vaginal sutures. A second attempt, after which a catheter was allowed to remain in the bladder for twenty days, was entirely successful.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting Held May 22, 1897.

The President, J. WINTERS BRANNAN, M.D., in the Chair.

STRIPPING OF THE SEMINAL VESICLES FOR NOCTURNAL POLLUTIONS.

DR. FOLLEN CABOT presented a case of seminal vesiculitis. The patient was twenty-two years of age, and had been treated by him since last August. He came complaining of nocturnal emissions of which he had had, at times, two or more during one night. He had masturbated about four years ago, but the emissions had continued after he had discontinued the practice. He was extremely depressed and suffered from insomnia. He never had had any venereal disease. Rectal examination showed the vesicles to be enlarged, the right one particularly. Dr. Cabot had begun stripping the vesicles very lightly, but afterward had done it with more force. Soon after the first stripping the emissions became less frequent, and under general tonics his health improved. After each stripping there had been a very marked feeling of relief. On emptying the vesicles, and having the patient pass urine, there would be found, as a rule, a heavy deposit. At the present time, the vesicles are nearly normal, and the sediment quite scanty. The stripping had been usually carried out at intervals of about a week. The patient had been treated by medicines and by the use of sounds, but without benefit. The marked improvement in his nervous symptoms was exceedingly gratifying. At present, emissions occur at intervals of a week or two.

DR. F. R. STURGIS said that the case was evidently one of pollutions, and not at all one of spermatorrhea. It is in these cases that nervous symptoms usually predominate. Quite possibly the vesiculitis came from an extension of the inflammation from the prostatic urethra. The case was of special interest in connection with the paper which he was about to present. The cases of daily pollution are very difficult to distinguish from true spermatorrhea. It was unfortunate that no microscopic examination had been made of the strippings. Some physiologists are inclined to believe that the vesicles themselves have something to do with the formation of spermatozoa. It is possible that their presence in the vesicles may account for those exceedingly rare cases in which impregnation has followed shortly after the removal of the testicles.

DR. FREDERICK R. STURGIS then read a paper on
SPERMATORRHEA.

He said that formerly the term had been used to designate every species of seminal loss, whatever the cause. This he considered a mistake. Almost all cases of genuine spermatorrhea occur without any preceding nocturnal, or diurnal pollutions, and its origin can only exceptionally be traced to such pollutions. He offered the following definitions:

Diurnal pollutions are those instances of seminal loss which are attended by a certain amount of erection, a slight degree of orgasm, with sexual feeling, ejaculatory spasm, and a genuine emission, of which the patient is conscious. On the other hand, in spermatorrhea, there is no erection, no orgasm, no consciousness of emission, and no sexual feeling; all that he is conscious of is that his urethra leaks, more particularly at stool. Riding over a rough road, or rapid running may produce an emission, but this is not the case in spermatorrhea. In spermatorrhea, there is a pronounced dilatation of the mouths of the ejaculatory ducts.

The causes are principally: (1) Mechanic pressure; (2) inflammation extending from the deep urethra to the ejaculatory ducts; (3) inflammation of the prostate gland and vesiculæ seminales; and (4) affections of the nervous system. One of the best known and time-honored causes is thought to be the pressure due to straining and the passage of hardened feces. He was inclined to believe, however, that seminal loss is due rather to the forcible pressure made by the abdominal muscles, as the vesicles are not situated in a position which renders them liable to pressure from masses in the rectum. In the class of cases due to extension of the inflammation, the origin is usually onanism, or "withdrawal," sexual excess, and the use of irritating injections in the urethra. Inflammation of the prostate gland and seminal vesicles he believed to be an infrequent cause of spermatorrhea. When a discharge occurs in these cases it is found to be devoid of spermatozoa, and to possess the characteristics of the prostatic juice. Affections of the brain and spinal cord sometimes produce spermatorrhea. He had seen cases in which he could assign no other cause for the spermatic difficulty than a chronic myelitis, although he was free to admit that many cases are due to a local, and not to a general cause. When the nervous system seems to be at fault, the patients are not aware of the existence of spermatorrhea, but consult the physician because of a peculiar feeling of nervous depression after going to stool. These patients usually give a history of nocturnal incontinence of urine. It should be remembered that spermatorrhea sometimes occurs in persons perfectly healthy, and who are entirely unaware of the existence of such a disorder. He was inclined to believe that it is a more common occurrence than is generally supposed. He felt confident that the loss of semen is not the debilitating thing it is usually believed to be; he had seen it repeatedly in persons in robust health. He was incredulous regarding the occurrence of spermatorrhea as a result of continence. Spermatorrhea rarely occurs before the age of fifteen years. When the disease is of long continuance the semen becomes thin and watery, and the spermatozoa become imperfectly developed, and their motility much impaired. Shreds and vermiform bodies are not infrequently found in the urine. These shreds are pieces of mucous membrane which have been stripped off from the urethra, and have no necessary connection with spermatorrhea. They are found in other cases in which there is congestion of the mucous lining of the urethra. Sometimes hyalin cylinders will be found. They are to be distinguished

from hyalin casts from the kidney by the fact that they are about double the width of renal casts.

The symptoms are extremely variable. As a rule, the first symptom is a slight, sticky discharge after stool or urination, usually containing some spermatozoa. The nature of the discharge can only be determined by several microscopic examinations. The other symptoms are pain in the back, burning in the eyes, a feeling of drowsiness, and a nervous chill at the time of the seminal loss. When such symptoms are present, the physician should examine several specimens of urine, taken at different hours during the day, particularly after stool. His experience had taught him that persons suffering from spermatorrhea do not exhibit any loss of memory or intellect. The sexual powers are not necessarily affected. The majority of patients recover perfectly.

The successful treatment of this condition naturally depends largely upon the removal of the original cause. The use of tonics is often of service, and much benefit follows a careful restriction of diet, and the avoidance of irritating cathartics or clysters. The local treatment is of the most importance, and consists in the introduction of cold sounds, and allowing them to remain for some time in the urethra. He had found that little or no benefit results from the uses of instruments to be worn by the patient.

DR. S. ALEXANDER said that the definitions propounded by the reader of the paper narrows the subject very much, and while he was not yet disposed to accept them unreservedly, it seems to him to be a step in the right direction. At the present time, there is a tendency to confound sexual neurasthenia and local causes. He was glad to hear the statement made, that seminal loss *per se* is not harmful—he had long been of that opinion. It was very clear to him that there is no such disease as spermatorrhea; it is rather a symptom of different conditions of the urinary tract. From a clinical standpoint he felt positive that when there is seminal loss there is disease, not only of the prostatic urethra, but of the seminal vesicles, and that without disease of the seminal vesicles there is no spermatorrhea. His experience had taught him that antecedent to all seminal losses of this kind there exists a constitutional defect; in other words, spermatorrhea does not occur in a normal, healthy man. In a neurasthenic who has practised masturbation or unnatural sexual intercourse, the spermatorrhea is as much due to the neurasthenic condition as to the local condition. He was doubtful about giving a favorable prognosis in the vast majority of cases of true spermatorrhea. This was based on his personal experience, although he was aware that it is opposed to the general opinion. The cases which recover as a result of local treatment alone are exceedingly few. A person with true spermatorrhea requires careful treatment in order to restore his nervous system to a normal condition.

With regard to stripping the seminal vesicles in cases of true spermatorrhea, the speaker said that he believed it undoubtedly gives immediate relief to the symptoms; that when given with an assurance that there is to be a marked benefit, the patient's mind is set at rest, and as a

consequence, his nervous and mental condition improves. He believed, however, if the stripping is done without holding out such encouragement, this local treatment will only be of temporary benefit. He had not been able to give this assurance to his patients, and he had not had as good results as had been obtained by Dr. Eugene Fuller.

Dr. Alexander objected to leaving sounds in the urethra for twenty or thirty minutes, for he believed that all the beneficial effect can be obtained by the simple passage of the instrument into the deep urethra. The prolonged retention of the sound in the deep urethra, he was sure, produces extreme congestion—just the condition which should be avoided. For this reason, he believed that the stronger applications of silver to the deep urethra are harmful, and that the milder solutions, given more frequently, accomplish better results.

DR. RAMON GUITERAS said that he shared very much the same views as the last speaker. He had always considered spermatorrhea to be a disease in which there is a leakage of fluid containing a great many spermatozoa. Prostatitis, he considered to be a condition associated with a chronic prostatitis, the formation of exudate in the prostatic urethra, and the expression of this exudate, usually on straining at stool.

He then referred to some cases of spermatorrhea occurring in his practice. He said that some months ago a pale, sallow man had come to him complaining of a leakage from the urethra during work, and during urination and defecation. The urethra was found to be normal, and so was the urine. The prostate appeared to be normal. The man was treated with very hot rectal irrigations, and hot solutions of nitrate of silver in the urethra (1 to 16,000). Laxatives and tonics were also used. In two months the leakage had practically ceased. Another case was that of a man in robust health who, about eight months before coming to him, had noticed a leakage when in company with women, although he was able to have satisfactory sexual intercourse. The urethra was found to be normal, the urine clear, and the rectal examination negative. He received prostatic irrigations of hot, weak solutions of nitrate of silver, and in a month was perfectly well. Another case was that of a neurasthenic man who complained of seminal losses during the past two years, following a urethritis. Examination showed urethral stricture and shreds in the urine. The strictures were dilated and the urethra injected with silver solutions. He was well in three months.

DR. EUGENE FULLER said that he did not think the classification of sexual disorders given in the paper was at all satisfactory. The investigation of sexual disorders by repeated microscopic examinations of the urine and discharges seemed to him very unsatisfactory. The term "spermatorrhea" should be placed in the same category with "brain fever"—it should be discarded. This disease has never been placed on a definite pathologic basis, but upon a symptomatic basis. Whatever results he had been able to obtain in these cases had been from the faithful carrying out of a particular method, and not at all from hypnotic suggestion or faith cure. The finger of the surgeon should be educated to rectal touch, however re-

pugnant it might seem to be. Success in this method of palpation depends not so much upon the length of one's finger, as upon the strength of one's forearm, and the mode of making pressure upon the perineum. At first, the examining finger will become quite sore, but this will soon pass off, and the surgeon will be able to obtain much valuable information from this skilled, systematic examination of the rectal field. He did not think that seminal loss occurs at stool in perfectly healthy persons. In most of these cases there will be found a very catarrhal and thickened condition of the seminal fluid. It is, after all, only a symptom. Not infrequently these sexual disturbances come on after severe illnesses. Regarding the stripping of the vesicles, he said that he was aware that many who have tried it have not obtained good results; on the other hand, a number of well known surgeons have been satisfied with the method. It is largely a matter of special technic, and many do not acquire it; hence, the failures. It is a prevalent notion that nothing is accomplished by stripping unless there is a large return of abnormal spermatic fluid, but this is not the case. When there is much infiltration outside of the vesicles, a considerable and prolonged treatment will be required before much result will be observed.

DR. CABOT said that general practitioners often fail to secure good results, not because they omit to give good advice, but because they neglect to make a careful examination. In normal cases, scarcely any fluid will be obtained by stripping. After considerable experience with stripping of the seminal vesicles he felt positive that a fair percentage of the cases derive benefit from the treatment.

DR. STURGIS, in closing the discussion, said that he had endeavored to make clear in the paper that the condition was an atonic one, without any active inflammatory process. In his experience, there is little or no inflammation of the seminal vesicles, or prostate in spermatorrhea. He originally had thought that the simple passage of a sound is all that is required, but in these non-inflammatory cases there is much tolerance to instrumentation, and he was inclined to believe that the prolonged retention of the sound in the urethra is a decided advantage. It is very different from the cases of diurnal pollution. Cases of inflammation of the vesicles are entirely distinct from spermatorrhea. Unless there is some special reason, he would be opposed to continual "milking" of the vesicles. Undoubtedly, in many chronic inflammations of the vesicles, an occasional stripping will do good; in the majority of cases it will probably prove harmful rather than beneficial. The discharge of semen at stool he would hardly look upon as a catarrhal condition. In the larger proportion of cases he believed that constitutional treatment plays an important part. These patients tolerate much stronger solutions of nitrate of silver than patients with diurnal pollution. It is his habit to employ as strong solutions as twenty or thirty per cent.

DR. ROYAL WHITMAN read a paper on

SOME PRACTICAL REMARKS ON SHOES. (See page 198.)

DR. J. W. BRANNAN made some remarks on

FLUID VACCINE.

He said that the New York Board of Health claims one hundred per cent. of successful primary vaccinations with their fluid vaccine. Three weeks ago he had used it in vaccinating six adults, all of whom had good secondary marks. The vaccination was perfectly successful in every one of these cases—a rather unusual experience.

DR. J. H. HUDDLESTON said that he thought the present notion of immunity from vaccination is very different from what it had been a number of years ago. It is certainly true that some persons who have been successfully vaccinated at one time can again have a typical vaccination six months later. It seems as if the rubbing in of a good deal of virus makes a vesicle of somewhat larger diameter than when a small quantity of virus is used.

DR. GUIERAS remarked that for two years he had vaccinated on the Board of Health, and in no case had he prepared the arm antiseptically. In only two was there any infection—one an erysipelas and the other an abscess.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting Held March 2, 1897.

The President, B. SACHS, in the Chair.

REMARKS ON THE MORBID ANATOMY (CHIEFLY OF THE BRAIN AXIS) IN DEMENTIA FROM LUES.

DR. E. C. SPITZKA read a paper with this title. He said that while cerebral syphilis is recognized clinically in most cases by a certain uniformity of type, it is still so variable in its manifestations that each case must be regarded as a law unto itself. Cerebral syphilis being chiefly an arterial disease, and the nutrient vessels being chiefly terminal vessels, each thrombic or gummy arterial lesion constitutes almost an atrophy experiment. In this disease epithelial granulations are extremely common, and are of two varieties, *viz.*, (1) round, small, regularly distributed, and almost translucent; and (2) warty, firm, opaque, and interlacing. The latter are the older, and contain connective-tissue elements.

Dr. Spitzka then quoted the following case: J. R., forty-seven years old, married nineteen years, had been seen by him on January 21, 1881. The patient complained of weakness of the limbs and of fugitive pains in various parts of the body. On rising from bed they became less severe and disappeared after walking. There was reflex iridoplegia and pain; the knee-jerk was slightly more jerky than usual, but not exaggerated; there was no Romberg symptom. The ocular background was normal. There was right ptosis of extreme degree. The pupils were unequal. All the associate movements of the eyeball were normal. There was no marked tremor of the hands. The tongue was protruded steadily in the median line. There was no facial paresis. The urine was normal, and there were no bladder symptoms at any time.

He was seen at intervals during twenty months. At no time was it possible for him to remember facts when they were recalled to him by association, and at no time

was he unable to attend to the details of his business, yet all his acts impressed both lay and professional observers as automatic. His family noted an exaggerated irritability. Mixed treatment was prescribed, but was not carried out regularly. Four months after he was first seen he had an apoplectic seizure, which was followed by an insufficiency of the left rectus muscle. A second and similar seizure was followed by left ptosis. After the first attack, mercurial inunction caused prompt improvement, but not so after the second. Two days before death the speaker had seen him. For some days previously he had been constantly making the tour of the house, and when seen was busily engaged in ripping the binding from the furniture. He went into coma a few hours later, and died in this state. At the autopsy the dura and arachnoid were entirely normal. The vessels of the convexity were apparently normal. The basilar artery was slightly thickened in its anterior third, and the right posterior cerebral artery exhibited two yellow patches. The left ventricle was normal. The slope of the aqueduct of the third ventricle was filled with net-like and firm granulations. The posterior division of the fourth ventricle contained numerous warty granulations. The brain axis was preserved according to the methods then in vogue. Two sections were exhibited, *i. e.*, from the anterior pair of the corpora quadrigemina and from the crura. The chief nuclear changes in this case were limited to the posterior division of the pneumogastric nucleus. A child of the patient whose case has just been described came under observation with a distinct papular syphilide at the time of the father's death.

This case was contrasted with another, which exhibited a typical picture of parietic dementia. The syphilitic infection had occurred twelve years before death, but the mental disorder had lasted only fourteen months. Death occurred in an apoplectiform sequel of a delirious exacerbation. The fore-brain showed no marked lesion of the neural elements; there was, however, a marked proliferation of the "spider cells." In the brain axis were diffused proliferations of nuclear elements in the reticular formation of the pons, and there was actual cirrhosis in the raphe and in the course of the hypoglossal nerve. The speaker said that the difference of the location of the arterial lesion in the brain axis in cerebral syphilis determines whether the case is to be one of syphilitic dementia or parietic dementia. With the intensification of the process in the aqueduct the former is to be expected. The vessels of the reticular formation are not strictly terminal, and nutritive changes are apt to be followed by insidious and irritative damage to the tissues, and corresponding influences on the function and tracts there located.

THE PRESIDENT said that he had been much interested in these comparatively little known findings in the lower portion of the brain axis. During the past few years he had been impressed by a number of cases which, clinically, had the appearance of general paresis, but which, in their general course and development, proved to be entirely atypical. Then there is a class of cases which from the outset appear to be distinctly syphilitic, because associated with the mental symptoms are other symp-

toms known to be syphilitic, *e. g.*, oculomotor palsies and frequent epileptiform seizures. He had taken some pains to determine clinically the symptoms which would enable one to differentiate between the typical paresis and the cases which yield a more favorable prognosis.

Dr. Sachs then referred particularly to the case of a man who had been stricken about one and one-half years ago with very marked delusions of grandeur, and had become entirely unable to take care of himself and family. His memory forsook him, and he was compelled to choose between confinement abroad or an immediate return to this country. A few days after his return Dr. Sachs had seen him. At this time he presented every single symptom of parietic dementia. There was the characteristic speech and the immobility of the pupils, and he was unable to write his name, etc. These symptoms gradually increased. He was placed under the care of an able trained nurse, and during about six months there was no decided change. After this time a gradual improvement was noted, and at present, eighteen months later, he is entirely well and able to attend to his business. The only remaining symptoms are complete immobility of the pupils and absence of the knee-jerks. His mental condition now is entirely normal. This patient confessed to a syphilitic infection many years ago. He has two healthy children, and there is no history of miscarriages. This case, Dr. Sachs said, seems to present a very different clinical course from that of ordinary general paresis. Apparently the specific meningo-encephalitis might be recovered from. In the other cases which he had seen he had looked upon the ultimate prognosis as grave, but in the one just cited he was inclined to believe that the outlook was much more favorable.

DR. W. M. LESZYNSKY said that the experience of most observers with cases of parietic dementia is that there are remissions simulating recovery. During these remissions the improvement is so marked that often the patient is discharged from an asylum as "cured." Usually, however, there will be a recurrence within a year.

DR. W. GRANGER said that remissions in cases of paresis are observed both in the syphilitic and non-syphilitic. The case cited by Dr. Sachs was very different from those in which remissions usually are observed; the almost complete restoration of the mental condition in this case would seem to indicate the possibility of ultimate recovery. Remissions in paresis will not be found to be perfect if the conditions are thoroughly and searchingly investigated. The power of concentration, of continued work and of self-control in the annoyances of daily life, will be found defective, showing that there is not a full restoration of the mental integrity. It will be remembered that many years ago Dr. Henry Hurd, a careful observer, reported what was thought to be a cured case of general paresis. In the report of the case, however, it was noted that the man did not have his former energy and power of attention to details. After a remission of many years there was a recurrence and death ensued.

The President said that there is another order of cases of general paresis suggesting the possibility of the clinical symptoms being due to a true syphilitic morbid

process, and not to the ordinary morbid process of general paresis. This view had been suggested to him by the case of a man who had also been seen by Dr. Spitzka about ten years ago. At that time there had not been the slightest doubt of the existence of general paresis. The man has been in a condition of dementia, however, for eight years. The disease developed very soon after the initial lesion of syphilis. In this case it seemed to him that the dementia is due to a widespread meningo-encephalitis, with resulting sclerotic changes.

DR. SPITZKA said that cases like the one to which Dr. Sachs last referred, of the continuance of life without restoration of mental power, in which the typical symptoms of parietic dementia are present, are far from rare; there are at least a dozen illustrative cases now in this city. He had seen distinct remissions lasting fully four years, and a large number lasting for a year and a half. He would, therefore, wait at least two years before feeling very sanguine about the case referred to by Dr. Sachs. The persistence of the Argyll-Robertson pupil, or of the absence of the knee-jerk, is not, however, an obstacle to recovery, because they are the last to disappear; indeed, the condition might have existed before the case came under medical observation, or there was evidence of any disease. In the case specially considered in the paper, the lesions occurring in the very locality where one would expect the most serious, if not fatal, consequences, and yet had yielded the best prognosis. One of these patients had been seen by Dr. Seguin and his staff sixteen years ago when he was in a condition of coma justifying the statement that he was moribund. Another had been seen by one member of the society who had pronounced him dead nine years ago. In both cases glycosuria, with a large percentage of sugar, had persisted to this day. In the first case there was only one mental symptom, *viz.*, when the man shut his eyes he lost the sense of his identity. The other patient presented another singular anomaly, *i. e.*, he could remember every fact which had been brought to his mind up to the time of his comatose or apoplectic seizure with an accuracy which was very remarkable, and yet five seconds after he had answered such questions he could not tell what question had just been propounded to him. Dr. Spitzka said he had been puzzled to account for the fact that all past registrations should be intact in a man fifty-three years of age, and yet his judgment should be so little embarrassed that he should make application for the appointment of a commission to take care of his business. If there was a degenerative process in the cortex, it should have shown itself in eleven years by an abolition of recollections, or at least by an abolition of associations, or by impairment of the sense of identity, yet none of these things had occurred.

Regarding the effect of antisiphilitic treatment in these conditions, the speaker said that as long as there is improvement, or prolongation of life, or an increase in the number and length of the remissions following such treatment, he would hold the door of hope open regarding the curability of dementia. Those who argued that if cases of supposed parietic dementia recovered they could not

be examples of parietic dementia, belonged to another planet.

REPORT OF A FATAL CASE OF HEMORRHAGE INTO THE PONS.

DR. W. M. LESZYNSKY reported the following case: At 8 A.M., on January 23d, he had been called to see Mrs. X, fifty-five years of age, the mother of six grown-up children. It was stated that she had been in excellent health previously. Half an hour before his arrival, and after having taken a cup of coffee, she suddenly lost power on the left side and became dizzy. When seen by him consciousness was preserved. Her pulse was 86, and of high tension; respirations 24 and regular, and temperature 99° F. in the mouth. The heart action was forcible and indicated well-marked cardiac hypertrophy without valvular disease. The lower facial muscles were paralyzed on the right side; on the left, the lower facial muscles were in tonic spasm. Both pupils were equally contracted to about 1.5 mm., and were absolutely immovable. She could not voluntarily elevate the left upper eyelid, but could close the right lids. The left eyeball deviated outward; the right was in parallelism. The tongue was protruded in the median line. The left upper extremity was paralyzed. Sense and motility were normal on the right side; the left knee-jerk was feeble. The patient insisted that the vertigo, hemiplegia, and inability to open the left eye occurred simultaneously. During the next hour and a half Dr. Leszynsky remained at the bedside and there was no sign of mental hebetude or any change in the symptoms. The urine contained a large quantity of albumin, and many granular casts and broken-down red blood-corpuscles. When seen again, at 1 P.M., she was completely comatose, and in a cold perspiration; there was complete relaxation of the paralyzed extremities. The right forearm was flexed upon the arm very rigidly. Both knee-jerks were exaggerated. Pulse 84, respirations 24, and temperature 99.2° F. Venesection was suggested, but was delayed until 8 P.M., owing to the absence of the family physician. There was then complete relaxation on the right side, and the temperature was 103.4° F. Sixteen ounces of blood was taken from the right median basilic vein, and the stream of blood indicated great pressure. At midnight the pulse was 120, respirations 40, and temperature 101.8° F. in the axilla. At 4 A.M. the temperature was 105° F., and death occurred at 6.30 A.M., with a temperature of 107° F. No autopsy was permitted.

Dr. Leszynsky said that he thought it was questionable whether free venesection could have saved the patient, even if it had been undertaken very early. It apparently was one of those cases of chronic interstitial nephritis with pronounced cardiac hypertrophy, without special symptoms, until cerebral hemorrhage unexpectedly terminated life.

REVIEWS.

ELEMENTARY BANDAGING AND SURGICAL DRESSING FOR THE USE OF DRESSERS AND NURSES. By WALTER PYE, F.R.C.S., late surgeon to St. Mary's

Hospital. Revised and in part rewritten by G. BEL-LINGHAM SMITH, F.R.C.S., Surgical Registrar Guy's Hospital. Seventh edition. Pp. 218. Philadelphia: 1897.

IN these days of large text-books it is an agreeable surprise to take up a little book which, in spite of its modest title, contains a fund of valuable information. In this well-illustrated little volume is to be found a comprehensive description of the methods of bandaging, and of splints; of the dressing and suturing of wounds, the method of making poultices and fomentations, and the dressing of simple wounds; together with the treatment, in the first instance, of accidents and emergencies, such as fractures, hemorrhage, shock, poisoning, etc. We are surprised that the author still clings to the use of perchlorid of iron—as a last resort—as a styptic. Nor can we quite agree with him when he states that a silicate of soda dressing will set in three to four hours; in our experience it has usually taken twelve to twenty-four hours. We suppose it is a printer's mistake that on page 62 we read of the plaster jacket as recommended by Dr. Sayres, instead of Dr. Sayre.

We are not surprised that the book has already reached its seventh edition. It is the best of its kind we have ever seen, a handy little volume which should be in the pocket of every medical student.

RETINOSCOPY (SHADOW TEST) IN THE DETERMINATION OF REFRACTURE AT ONE METER DISTANCE WITH THE PLANE MIRROR. By JAMES THORINGTON, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic; Ophthalmologist to the Vineland Training School for Feeble-Minded Children, etc. Twenty-four illustrations. Philadelphia: P. Blakiston, Son & Co., 1897.

THIS concise and lucid treatise is an abstract of the author's previous writings and lectures on Retinoscopy, delivered during the winter course on Ophthalmology at the Philadelphia Polyclinic. Although it is primarily a text-book for college students and post-graduates, ample material is given by which the practitioner may gain a working knowledge of the method in his own office. The little volume is abundantly illustrated. A number of mechanic aids to the test—some of the author's device—give an additional value to the book.

A TEXT-BOOK OF BACTERIOLOGY. By GEORGE M. STERNBERG, M.D., LL.D., Surgeon-General U. S. Army, Ex-President American Public Health Association, Honorary Member of the Epidemiological Society of London, etc., etc. Illustrated by heliotype and chromolithographic plates and two hundred engravings. New York: William Wood & Co.

THE "Manual of Bacteriology," by the same author, has been widely and favorably known since its publication in 1892. This text-book is a revised edition of the Manual with a large part of the detailed descriptions of nonpathogenic bacteria omitted. It is intended for students of bacteriology and for use in laboratory investigation.

The book, comprising 690 pages, is well printed and

profusely illustrated. The illustrations are partly from original preparations and partly taken from illustrations in other bacteriologic works. They are well selected and greatly enhance the practical value of the volume.

The text-book is subdivided into four sections. The first deals with laboratory apparatus, staining methods, culture media, photography of bacteria, etc. The second section deals with bacteria as a whole, describing conditions favorable or unfavorable for their growth; their products and the influence of disinfectants, blood-serum, etc., upon their growth. This portion includes a practical consideration of disinfection of infected clothing and rooms. The third section, comprising two-thirds of the volume, gives a detailed account of the varieties of pathogenic bacteria, the more important forms being very fully described. The final section considers briefly the saprophytic bacteria occurring in the air, water, earth, etc.

The method of preparing the work from original monographs has both advantages and disadvantages. The inclusion of the partially contradictory results obtained by different investigators allows the experienced bacteriologist to determine by experience the amount of truth in each statement. For the beginner, however, it is necessarily somewhat confusing. Even the latter is apt to obtain a broader and more correct idea of bacteriology from such a method than if points still unsettled were arbitrarily put down as certainly established.

When, however, earlier conclusions have been shown to have been certainly incorrect it would have been better to omit the incorrect observations. Thus, in the article on diphtheria, on page 373, it is stated that "diphtheria bacilli occur only in diphtheria and probably never in healthy throats," while on page 385, in "additional notes," it is stated that "later investigations have shown them to be frequently present."

In some portions rather important omissions occur. Thus, the best media for growing streptococci, a mixture of blood-serum and bouillon, is not mentioned, and the great difference in the amount and kind of virulence possessed by different streptococci is inadequately stated.

A few incorrect statements have been allowed to remain. Thus, it is stated on page 356, that "no other organism than the typhoid bacillus has been found to be present in deeper portions of the intestinal glands involved in this disease or in the internal organs"; also, in another portion, that "diphtheria bacilli are never present in the internal organs of those sick with diphtheria."

As a whole, the book is deserving of high praise, and it appears to us to be the best work on bacteriology published in the English language.

DEUTSCH'S LETTERS. A Practical Method for Easy and Thorough Self-Instruction in the German Language. By SOLOMON DEUTSCH, A.M., Ph.D. Second revised edition. New York: J. H. Vail & Co., 1896.

DR. DEUTSCH'S book on this subject is well-known. Its first edition is found in the libraries of many physicians who sought to learn the German language by a study of its pages, and we are glad to see that the neces-

sity for a second edition has arisen. A key to the German exercises has been added, and the book is bound to have a wide sale, for it is the most practical work on the subject with which we are acquainted, and we can testify to its usefulness and worth.

A MANUAL OF THE PRACTICE OF MEDICINE. Prepared Especially for Students. By A. A. STEVENS, A.M., M.D., Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania, Demonstrator of Pathology in the Woman's Medical College of Pennsylvania, etc. Fourth edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders, 1896.

THIS book is a concise and exhaustive manual on the practice of medicine, and has been specially designed for students preparing for graduation and hospital examinations. Some important additions have been made, many of the articles have been rewritten, and an appendix has been added, in which the author briefly describes the usual methods for examination of the blood and gastric contents.

It is important in a work of this kind to eliminate theories and to give due prominence to facts which the student is required to know. This has been accomplished in a happy manner, and the condensed form of statement also makes the book valuable for the busy practitioner as a handy work of reference.

ARCHIVES OF CLINICAL SKIAGRAPHY. Edited by SYDNEY ROWLAND, B.A., Cambridge, late Scholar of Downing College, Cambridge, etc. London: The Rebman Publishing Co., Ltd., 1897.

THE application of Röntgen photography to the varied purposes of clinical diagnosis has made such great strides during the past year that the special literature of skiagraphy has assumed unexpected proportions.

The publication under consideration appears somewhat in the form of an atlas containing a series of half-tone reproductions of skiagraphs, with descriptive text, illustrating interesting or unusual applications of the new photography to medicine and surgery. The preponderance of the latter department is shown by the fact that five plates out of eight deal with fractures or their sequelæ.

Interesting abnormalities are shown in the skiagram of six toes in each foot, and an unusually clear picture is that of a double monster, in which the two breeches and lower extremities are quite separate, while the four upper limbs are fused. The skiagram shows two faces, one of which is perfectly formed, the other incompletely developed and represented only by a pair of ears fused together, two bases crani, and two distinct columns of vertebræ with their anterior surfaces facing each other. The original plates were evidently unusually clear and sharp. The reproductions are as good as can be expected with the process used. The claim is made in the title that the illustrations are collotypes, whereas, in fact, there is not a single illustration by this process, the cheaper half-tones being substituted.

ORIGINAL ARTICLES.

THE TREATMENT OF CUTANEOUS CANCERS.¹

By J. B. MORGAN, M.D.,
OF AUGUSTA, GA.

THREE of the recent theories of the etiology of cancer are at present claiming more than passing attention throughout the scientific world, each having its plausible side and each its warm advocates. "Asymmetric Cell Division in Cancer and its Biologic Significance," is the title of a thesis by Hanseman, wherein the theory of indirect cell division is advanced. The second theory, which has a great many advocates who differ slightly, however, as to details, supposes that an intracellular or intranuclear parasite (according to some, a coccidium; to others, a psorosperm, and to still others, a gregarina) infests the tissues, and through its presence induces a lawless growth of epithelial and connective-tissue elements. The parasitic theory is the third one. This supposes that the cancer parasites are animals, and that there are no epithelial elements at all in these neoplasms, the polymorphous bodies found in the growth being in reality not epithelial cells but the parasites themselves, and that these parasites produce a toxic substance, known as cancrioid, which is responsible for the so-called cachexia.

Such widely different ideas would seem to indicate that the final solution of the subject has not yet been reached. So far as the subject of this paper is concerned the treatment here suggested is equally applicable whichever of these theories is accepted. Cancer still remains one of the most dreaded and fatal diseases known to science. While this unfortunately is true, and while as yet no specific in the treatment of the disease has been discovered, on the whole the outlook is decidedly encouraging. More is known about the nature of cancer, macroscopically and microscopically, than was known even five years ago, and it is now treated more successfully every year. Some things which we have learned concerning it are of the highest importance and profoundly influence our present treatment. For instance, it is now almost universally held by all leading pathologists that cancer is primarily a local growth, and that all cancers can be cured if thoroughly removed before the epithelial cells have infiltrated the connect-

ive tissue and neighboring glands, for it is generally conceded that it is the proliferation and infiltration of the epithelial cells which causes cancer to invade other tissues and organs and become disseminated throughout the body. This being the case the only treatment which offers anything like a cure is the one which has for its object the early and complete removal or destruction of all the morbid elements.

Another important fact connected with cancer, which is also an unanswerable argument for its early and thorough removal, is its manner of growth. Non-malignant new growths, such as lipoma, chondroma, etc., originate from embryonic rudiments in an indirect manner as a result of an injury to the part; they are simple tissue-tumors and increase in size by continuous multiplication of existing cells, and as the tumor increases in size by centric growth, the tissues of the part in which it is situated are pressed upon until finally they become so compressed as to form a more or less distinct capsule within which the tumor is contained. Outside of this there is no infiltration of the tissues or peripheral extension growth. This capsule can easily be recognized, and the extent of an incision in a given case definitely determined, and we can know positively when all the tumor is removed.

A very different condition of affairs obtains, however, in connection with the growth of cancer. It does not spread by centric growth, producing a sharp, easily-defined margin, but by peripheral proliferation and by an infiltration of the tissue to an extent not recognizable by touch or unaided sight. There is no capsule enclosing such a growth, and no well-marked limit to the infiltration. The increase of the tumor by continuous growth of the peripheral cells and infiltration of the surrounding tissues, not *en masse*, but gradually and without order, as regards the line of limitation, produces a condition entirely different from that produced by centric growth as occurring in the simple tissue-tumors.

A fibroma is due to the growth of fibrous cells, the process being almost identical with that which occurs in the healing of a wound. A lipoma is nothing more than a fibroma in some of the cells of which are deposited fat globules; the oil in the cell has simply pushed the nucleus to one side. A fibrous cell does not possess the power of infiltration as does the

¹ Read before the Georgia State Medical Association, April 21, 1897.

epithelial, and is, therefore, self-limiting, movable, and, as a rule, benign. In the one case the cells grow from the center and bulge out, and are dependent upon some form of external irritation; in the other, the cells grow on the surfaces and dip into the tissues, due to some irritation acting within the growth. In the one case the pathologic process is sharply defined and its limits restricted by the protective capsule; in the other, the diseased cells are unconfined and free to wander where they will.

The therapeutics of cancer are, to say the least, in a very unsettled state and in every way highly unsatisfactory. A great many remedies have been tried, and all have proved more or less complete failures. No surgeon would now think of relying on general constitutional remedies, except in cases where the knife or some good equivalent could not be used. If the etiologic factor of cancer is parasitic, we may hope that in the future some agent will be discovered which will kill the germ or make its habitat unfavorable to its continued existence, but at present our only reliance is in local treatment—the prompt and complete removal or destruction of all diseased tissue. To accomplish this end surgical means have been almost exclusively employed. In the removal of ordinary benign tumors surgery certainly offers us the best means and the greatest success, for in simple tumors the growth, when favorably situated, can always, and with absolute certainty, be removed by excision, but in cancer, in which there is no limiting membrane and no sharply defined guide as to the extent of the infiltration beyond the tumor-mass, other means than the use of the knife may more properly be indicated for its successful removal.

The object of this paper is to endeavor to emphasize this point. I wish to state here that I am a strong believer in the use of the knife in suitable cases, and frequently employ it. It has the advantage that, where an anesthetic is employed, it can be used without pain, the tumor can be removed quickly, and the wound heals rapidly. Again, there are certain portions of the body in which cancer may occur where employment of the knife seems to afford the greatest hope of success, as for instance, on the flexor surface of the forearm, the penis, and the scrotum. Unless seen early, in cases of cancer of the forearm and penis, amputation will probably offer the only relief. A great amount of tissue can be removed from the scrotum without injury to the patient, therefore the knife has decided advantages over any other form of local treatment for cancer of this locality, but in other situations, as the nose, cheek, or, in fact, any portion of the face, where the necessary amount of tissue cannot be re-

moved without producing more or less mutilation and deformity, the knife should not be used. The treatment of cancer by the knife is very far from satisfactory. It is true that if all of the diseased tissue is removed by this means the tumor will not recur, but practically, this seems very difficult to accomplish. It is a fact that very frequently there is a recurrence of the disease after a few months or possibly a year or two. I have seen but few instances of skin cancer removed by the knife which have not recurred within two years. It is well known that local recurrences after knife operations nearly always begin as small, hard, and well-defined nodules on the very edge of the scar, being partly in the normal and partly in the cicatricial tissue. Attention has been drawn to this fact recently by a number of our most eminent surgeons, and they suggest that the operation should be of a more sweeping character.

It is difficult to remove a malignant tumor without the knife cutting into some portion of it, therefore, the blade must be infected by some of the epithelial cells, and it is easy to conceive that some of them may be left embedded in the healthy tissue in spite of careful antiseptic washing and closure of the wound after all of the original tumor has carefully been removed, but with the germ of the recurrent disease unintentionally sown in good soil. On the other hand, if a few of the scattered epithelia happen to be situated outside of the line of incision there is no inflammatory process to weaken or destroy them. There are a number of authentic cases of cancer being destroyed by the results of inflammation alone. It is no uncommon practice now to produce inflammatory conditions for this specific purpose, but in this day of asepsis and antisepsis the wound heals by first intention, and if a single cancer cell is left even at the margin of the wound it is not destroyed, and during the healing process, when an unusual amount of nutrition is furnished to the part, this epithelial cell is placed in a specially favorable condition to grow and increase.

These and other reasons would seem to indicate that the knife is not always the best means for the removal of malignant growths. There is no doubt, I think, that the employment of such escharotics as caustic potash, chlorid of zinc, and arsenious acid is fully as efficient as the knife in any case, and has decided advantage over it in many instances. I am sure that not a few will regard this as rather an extreme statement. I am fully aware of how the profession in general is prejudiced against those ignorant or designing charlatans who advertise themselves as "Cancer Doctors," "Cancer Specialists," etc. I fully share in this proper detestation of such quacks and their methods, but very few will dispute the

fact that even they do sometimes cure cancer, and that, too, in many instances without any kind of knowledge of the disease treated, or of the therapeutic action of the remedy employed. Because a certain kind of remedy or a certain treatment is employed by blatant quacks, is no argument that there is not good in it. The corner-stone of rational medicine is to accept facts wherever they are found.

My personal observation in the use of caustics in the treatment of cancer may be of but little value, as I have not treated many cases, and only those coming to a physician in general practice. I am indebted to Dr. A. R. Robinson of New York for much that is good in this paper. But for his teaching I am sure that I would have continued to advocate the use of the knife in the treatment of skin cancers, notwithstanding that when I have used the knife I have had more recurrences than cures. During the last four years I have treated fourteen cases of skin cancer with caustics, and in not a single instance have I seen the slightest indication of a recurrence. Five of the patients were operated upon from three to four years ago, three from two to three years ago, and the other six have been treated within the last two years. One of the number died from pneumonia three years after having been operated upon; the others are all living and in good health.

Caustics of various kinds have been employed for a long time in the treatment of cancers both by cancer quacks and the regular medical profession. I am satisfied that their use in this connection has not received a fair and impartial trial at the hands of the latter. Most physicians have condemned their use without a trial, or, if employed at all, it has been in a very crude and imperfect manner. To my mind, there are several good reasons why caustics should be given a full, painstaking trial in the treatment of skin cancers. In the first place, cancer is a most dreadful disease and fearfully fatal, and anything which offers a reasonable hope of cure should be welcomed gladly. In the second place, and if for no other reason, their use should be taken out of the hands of ignorant charlatans and placed in the hands of the regular profession, where they properly belong.

If the cure of cancer is dependent upon its early removal, the caustic treatment has an additional advantage over the knife, since a great many timid patients who shrink from a cutting operation, with a little tact upon the part of the operator, will readily consent to the application of a caustic paste. There is no doubt that some caustics have somewhat of an elective action, and all of them cause less destruction of tissue, and produce less deformity than does the knife. Again, if the products of inflammation have

any influence in modifying or destroying the growth of cancer cells, the fullest benefit and advantage of it is obtained in the use of caustics.

These caustics are quite poisonous, and when employed in a careless or incompetent manner are likely to do great harm. Weak caustics, too, do infinitely more harm than good. By their use only a portion of the tumor-mass is destroyed by one application, and the resulting inflammation is slight and gradually loses itself in the surrounding tissues. This has the effect of simply stimulating the growth, and hence of causing a more rapid proliferation and infiltration of the epithelial cells than existed before the cauterization, but with such caustic agents as caustic potash, chlorid of zinc, and arsenious acid, the tissue can be destroyed to a greater or less extent and as rapidly as is desired.

As a result of the application of any one of these caustics there is complete destruction of the tumor-mass and an intense widespread inflammation which extends far beyond the limits where the knife would usually be employed. I am fairly well convinced that from the use of these caustics there is formed in the tissue cauterized a toxalbumin which is destructive to the cancer cells or to the parasites of cancer, if such exist. It may be the inflammatory process alone, which produces the desirable results, but when enlarged lymph-glands at a distance from the cancerous tumor diminish in size after the caustic has been applied it is difficult to avoid the conclusion that such an agent must be present and active. The following is a case in point:

Mrs. M. H., aged fifty-five years, came to me about $3\frac{1}{2}$ years ago with a recurrent epithelioma of the right breast, the original growth having been removed eight months previously in rather an imperfect manner. The axillary glands had not been removed as it was said they were not enlarged at the time of the operation. They were now enlarged, however, and I advised a second and more thorough removal of the tumor and glands with the knife. She firmly declared that she would rather die than undergo a second cutting operation. I then applied Marsden's paste and left it on for twenty hours, and in seven days the entire tumor sloughed out. The wound healed in about eighteen days. At the time I dismissed her by the most careful examination I could not detect a single enlarged gland in the axilla.

It is now more than three years since this patient received the treatment and there has not been a sign of recurrence. I have operated on two primary cancers of the breast since that time, with caustic potash, in one case the glands being slightly enlarged. The glandular enlargement entirely disappeared in about three weeks, and in neither case has there been anything but the most favorable result. In the near

future I intend to publish the results of treatment in other cases.

Each of the escharotics mentioned seems to have special indications peculiar to itself. For instance, if rapid work is desired, caustic potash is indicated; in extensive work, chlorid of zinc has advantages, and for sure, safe work, in the majority of cases, arsenious acid is the most desirable agent we can employ. Caustic potash quickly liquefies the tissues, and at one sitting a very large tumor can be destroyed. Its action, however, extends farther than the part to which it is directly applied, and its use is followed by marked inflammatory changes in the surrounding parts which may or may not lead to destruction of the tissue. If the latter occurs, a wound results as large as that usually made by a knife, but with care in its use the destruction of the surrounding tissue from the intensity of the inflammation may entirely be avoided, and only the tumor proper be destroyed. The amount of inflammation following the use of caustic potash is said to be a valuable guide as to the extent and amount of the epithelial infiltration. This seems plausible, since the inflammation must depend upon the vulnerability of the tissues, and the vulnerability upon the condition of nutrition of the part, and this condition is directly the result of circulatory disturbance, caused by the extent of infiltration by the epithelial cells. The agent is a valuable one when positive results are desired during one sitting. As a rule, it leaves more cicatricial tissue than either chlorid of zinc or arsenious acid. Its use is contraindicated near the eye or upon the nose. Its application is attended by much pain, but a general or local anesthetic can be employed, and in this respect it has no disadvantages as compared with the knife.

Chlorid of zinc as a caustic may be used in stick form, in solution, or in a paste. It causes more pain than either caustic potash or arsenious acid. Chlorid of zinc is not thought to have any decided elective action for pathologic tissue, but destroys both normal and pathologic tissue with an almost equal degree of rapidity. On account of its slower deliquescence and slower action, it has some advantages over caustic potash. In epithelioma of the roof of the mouth, of the lip, or when situated near the outer or inner canthus of the eye, on the lid, a pointed stick of chlorid of zinc may be used more effectively and with greater precision and safety than any other caustic. Caustic potash or any form of caustic paste is apt to cause too much inflammation when used near the eye, and is not enough under the control of the operator. A fifty-per-cent. solution of the chlorid of zinc may be injected into any desired portion of a cancerous growth, or a paste may be employed for its

destruction. Bougard's paste is one of the best that we possess in the treatment of small cutaneous cancers. It is prepared as follows:

R	Wheat flour	{	aa	.	.	.	.	3 i
	Starch							
	Arsenious acid		.	.	.	.		gr. x
	Hydrarg. sulph. rub.	{	aa	.	.	.		gr. xxxv
	Ammon. mur.							
	Hydrarg. bichlor.		.	.	.	.		gr. iv
	Zinc chlorid (cryst.)		.	.	.	.		3 i
	Water (hot), about		.	.	.	.		3 i ss.

(Ten grains of cocain muriate may be added to this.)

The six first-named ingredients should be mixed together and finely powdered in a glass mortar, the zinc chlorid, after being dissolved in the hot water, then being added and the whole rapidly mixed by means of a pestle. It should then be allowed to stand for twenty-four hours, when the paste will be ready for use. It is spread thickly on a piece of muslin and left upon the part for twenty-four hours. If the first application is not positively successful, the second should be made within a few days. This paste can be applied to a large surface at one time, as there is no danger of poisoning. If the surface of the tumor is hard, or the epidermis unbroken, it is better before applying this, or any other form of paste, to lightly apply a stick of caustic potash. The action of the paste is then more prompt and sure. After the tumor has sloughed out, which will occur in from three to ten days, the wound may be treated with any simple protective salve or antiseptic dressing.

The caustic above all others which has the widest range of usefulness, and from which the most satisfactory results in the treatment of cutaneous cancers are derived, is arsenious acid. It is usually employed for this purpose in the form of a paste, known as Marsden's paste, and consists of equal parts by weight of arsenious acid and powdered acacia, rubbed well together, with enough water added to make a paste about the consistency of rich cream. This should be spread upon muslin or rubber plaster in a layer about one-quarter of an inch thick and applied so as to extend beyond the edge of the visible tumor in every direction. It should be kept in position for from fourteen to twenty hours. From four to six grains of cocain should be incorporated with each dram of this paste. It is not as good as chlorid of zinc in cases of cancer of the lip or of mucous membranes on account of the danger of poisoning by absorption. The fact that the paste may be applied to the healthy skin without producing destructive results shows that it has an elective action for diseased tissue. It acts quicker and with less pain than the chlorid of zinc. To my mind, Marsden's paste is preferable to all other forms of caustics and may be

regarded as almost a specific for skin cancers, if they are treated early. The wound which remains should be treated as in the case of chlorid of zinc. If the tumor is large, or the wound does not heal kindly after a reasonable length of time, a second or even third application of the paste should be made. To apply these caustics successfully demands a certain amount of experience, but this any one can acquire after applying them two or three times. The greatest cause of failure in their use is the neglect to treat the case energetically until thoroughly satisfied that all diseased tissue has been destroyed.

THERMIC FEVER AND HEAT PROSTRATIONS.¹

BY FRANK WHITFIELD SHAW, M.D.,
OF BROOKLYN, N. Y.;

ATTENDING PHYSICIAN TO THE BROOKLYN ORPHAN ASYLUM; ASSISTANT ATTENDING PHYSICIAN TO THE METHODIST EPISCOPAL HOSPITAL.

THERE probably is very little, if anything, new that can be said regarding the effects of high atmospheric temperature upon the human body, but as the summer of 1896 demonstrated that we are by no means removed from its dangers, and as my opportunities for observing its effects during July and August were rather unusual in their completeness, it has seemed that possibly it might be instructive to review the condition in connection with a few typical examples. The cases to which I refer, thirty-two in number, occurred during the service of Dr. G. R. Butler at the Methodist Episcopal Hospital, Brooklyn, and it is by his courtesy that I am permitted to report them.

The epidemic character of the outbreak of heat prostration and its compression within the limits of a few days, produced a very vivid impression, which would have been entirely lacking in the presence of only a few isolated cases. This, perhaps, cannot be better illustrated than by the fact that at one time at the gates of the hospital there were two ambulances, one ice cart, and a delivery wagon, each containing one or more patients. For a few days the rush was so great that many of the patients who had suffered a mild attack, after remaining at the hospital for a few hours were allowed to go home, no record being kept of them. It would be natural to ask why, at this particular time, there occurred such a large number of cases attended by such fatal results. The high temperature alone does not explain it, because, as is well known, people living upon the high table-lands of Abyssinia and in the dry regions of Texas are much less liable to attacks than those living in the lowlands and in sections bordering on

the seacoast. A dry atmosphere increases tolerance of high temperature, while moisture diminishes it. During July and August, 1896, in addition to the high temperature, there was an unusual degree of humidity, rendering rapid cooling of the body impossible. Adding to these conditions the accepted predisposing causes of heat prostration—race, excessive bodily fatigues and intemperance—the etiologic factors are about complete. These conditions in combinations exhaust the so-called inhibitory heat-center so that it soon becomes greatly weakened, if not temporarily destroyed. The existence of this distinct heat-center in the brain, however, is quite seriously questioned by many accurate observers, while there are others, among whom is Gower, who give apparently satisfactory evidence of the existence of a center which does have the regulation of heat as its function.

Ott speaks of thermotaxic centers in connection with typhoid fever. Concerning heat and fever in general, some interesting experiments with rabbits, both fasting and in normal condition, are reported by Nebelthau,¹ the principal conclusions being as follows: (1) In fever there may be an increase both of production and loss of heat; (2) there is yet no proof that fever is ever due to retention of heat; (3) regulation of temperature is not wholly abolished in fever; (4) the normal proportion between the amount of heat lost by evaporation of water and by radiation and conduction is not altered in fever. Laveran² (quoted by G. N. Stewart) attempted to elucidate the cause of sunstroke by observing the effect of high temperature on dogs at rest and doing work. The latter were much sooner and more seriously affected and the rectal temperature rose more rapidly. At the time of death the rectal temperature always was at least 45.5° C. Death was not due to coagulation of myosin or to asphyxia. The heart sometimes began to beat again after the chest was opened, but transfusion of blood never restored the animal. The only explanation of the fatal result seemed to be in the action of heat on the nervous system, perhaps paralysis of the ganglia of the heart. The conclusion reached by Wood is that heat exhaustion with lowered temperature represents a sudden vasomotor palsy, or a paralysis of the center in the medulla. On the other hand, thermic fever is held to be due to paralysis under the influence of the extreme external heat of the center in the medulla which regulates the disposition of the bodily heat. Owing to this disturbance more heat is produced and less given off than normally. (Osler.)

Males, owing to their mode of life, are more sus-

² Pfäuger's "Archives," Bd. lviii, 229.

ceptible to heat influences than females. The greatest number of cases of sunstroke or prostration occur in those between twenty and fifty years of age. That excessive bodily fatigue is a very important etiologic factor is well shown by Barclay in his account of a forced march of more than eleven hundred miles, during the very hot season, by the English troops in India. No cases of heat exhaustion occurred until more than nine hundred miles had been traversed, and the men were greatly emaciated from lack of proper food. During this period the temperature at times was as high as 105° F. at midnight. Cases of prostration then began to occur rapidly, and before the weather became cool many of the men died.

Intemperance, or even the moderate use of alcohol, especially in those whose occupation requires a considerable amount of bodily exertion, is an important factor. With but few exceptions, all the male patients treated at the Methodist Episcopal Hospital, for sunstroke or prostration, had used beer and whisky freely, two of those who died developing delirium tremens after the thermic symptoms had almost entirely subsided.

Prostrations by heat should be divided into three classes: (1) Simple heat exhaustion, in which there is a normal or subnormal temperature from the beginning; (2) cases in which the temperature does not rise much above 101° or 102° F.; and (3) cases of true sunstroke, in which the temperature ranges from 106° to 113° F., and in which partial or complete insensibility is present, convulsions or complete paralysis of the voluntary muscles being a prominent symptom. Martin of Paris classifies these cases: (1) As a cerebrospinal type, characterized by symptoms of intense congestion, injection of the conjunctivæ, convulsions and coma; (2) as a cardiac type, in which there is pallor of the face and profuse sweats, death occurring from arrest of the heart; and (3) those of a pulmonary type, in which, in addition to other symptoms, there is anxiety, dyspnea, and asphyxia. The few cases which I report herewith are illustrative of these types.

CASE I.—A plumber, twenty-two years of age, was overcome while walking in the street. On admission his temperature was 98.2° F., respirations, shallow but regular, 20 to the minute and pulse small, rapid, and feeble, 120. His pupils were dilated but did not readily react to light. He was rational, with a tendency to drowsiness, had considerable headache, and was very weak, especially in the legs. The extremities were cold. After thirty-six hours he had responded to simple medication and the external application of heat, and was discharged cured.

CASE II.—An iceman, twenty-five years of age. He had always been a hard worker and a moderate

drinker. He had not felt well during several days previous to the attack but had continued at work. He had been unable to sleep during the previous two nights, and six hours before admission to the hospital had begun to feel dizzy and weak. In spite of this he had been exposed to the hot sun all the morning. On admission, his temperature was 97° F., respirations shallow and rapid, and pulse irregular and feeble. His pupils were dilated. He was extremely prostrated, being unable to speak aloud, his muscles were relaxed, and his skin dry and cold. He was discharged, cured, on the second day.

CASE III.—H. R., aged forty, single, always had been an unusually heavy drinker, at times drinking as much as one and one-half pints of whisky during twenty-four hours. During the three or four days previous to his admission he had drunk to excess and had taken but little food. When brought to the hospital he was unconscious, his temperature being 110° F., pulse 130, and respirations labored and shallow. His pupils were contracted to a marked degree, face pale, skin hot and covered with profuse perspiration, which had a urinous odor, and all of the voluntary muscles relaxed.

He was immediately placed in a cold bath for fifteen minutes, and half an hour later regained consciousness, his temperature then being 101° F. The following day he appeared to be doing well, but toward evening his temperature rose to 102° F. and he became violent. During the night he developed well-marked symptoms of delirium tremens and died shortly afterward.

In contrast to the first two cases is the recorded history of a powerful man working in a hot, confined space at the Philadelphia Exposition in 1876. He was attacked without warning and became violently delirious. His temperature was 95.2° F., pulse rapid and fluttering, muscular relaxation was complete, and the surface of the body was covered with a profuse cold sweat. Boudin reports a series of one hundred cases of thermic fever occurring on board a French war-vessel, a majority of the men being attacked while lying in their bunks. Bonninman says that in India the greatest number of cases occur in those who are not exposed to the sun.

The diagnosis of heat prostration is ordinarily not difficult. The usual symptoms are extreme prostration, restlessness, and, occasionally, slight delirium. The body may be cool and dry or bathed in profuse perspiration. The pulse is small, rapid, and feeble, the respirations weak and shallow and the temperature subnormal, normal, or slightly above. In thermic fever to these symptoms are added unconsciousness, complete muscular relaxation, or severe tonic or clonic spasms, and more or less interference with respiration.

Guiteras says that in certain of the Southern States there exists an affection known in some localities as

"country fever," and in others as "Florida fever," which sometimes is mistaken for malarial or typhoid fever. He considers it to be entirely distinct from these diseases, and has given it the name of "continued thermic fever."

There were but few sequelæ to the cases treated at the Methodist Episcopal Hospital, and these were unimportant. The literature relating to this subject, however, is quite full, and a large number of conditions are mentioned to which thermic fever is assigned as the predisposing cause. Among these may be mentioned intolerance to the sun's rays, difficulty of speech, meningitis, general or local muscular tremor, wrist and foot drop, muscular atrophy, changes in electrical reaction of muscles, long-continued acceleration of pulse and respiration, impaired nutrition, indigestion and anemia, headache and vertigo, tenderness of the spine, epilepsy, hemiplegia, cutaneous anesthesia or hyperesthesia, enfeebled memory, deafness, and a variety of heart lesions, both organic and functional. (Barlow.)

The treatment of these patients, except in the case of those having a subnormal temperature, consisted in the application of cold in the form of ice-caps, abdominal coils or the ice-water bath, and the administration of strychnin, atropin, digitalis, spartein, or nitroglycerin, according to the indications present. All patients with a temperature of 103° F. or more were given a cold bath. This was administered as follows: As soon as possible after admission the patient was stripped, wrapped in a sheet, and lowered into a movable bath-tub containing water in which was floating large pieces of ice. Cold compresses were applied to the head, and his body was then vigorously rubbed with ice, this being kept up until the rectal temperature had been reduced to 102° or 101° F., or until symptoms of shock developed, when he was removed from the bath, wrapped in a dry sheet, and put to bed. The rectal temperature was taken every half hour, and the bath was repeated at intervals, if necessary, until the temperature showed a disposition to remain near the normal point. As a rule, it dropped from one to three degrees each time the patient was taken from the bath. In a majority of instances consciousness was regained while in the bath or immediately afterward. It is very essential in carrying out this treatment that a sufficient number of assistants be available, for the constant changing of the compresses, and the rubbing of every portion of the body with ice is of very great importance.

In a few instances the cold bath was tolerated for a short time only, and one patient had to be removed from the tub immediately after immersion on account of the shock produced. Another patient whom the

bath did not benefit, and who subsequently died, had two intestinal hemorrhages, which possibly might have been prevented had active bleeding been resorted to, a procedure which Weir Mitchell mentions as having been successfully adopted in a case of his own.

Antipyretic drugs were not administered. These never should be relied upon as a substitute for the application of cold in these cases. The number of patients treated was thirty-two and the number of deaths nine, two of the patients being moribund when admitted. The percentage of recoveries is somewhat larger than that reported by Osler in connection with cases occurring at the Pennsylvania Hospital, Philadelphia, during the summer of 1887.

ON THE OCCURRENCE OF PRIMARY TUBERCULOSIS OF THE KIDNEY, WITH SPECIAL REFERENCE TO A PRIMARY MILIARY FORM.

BY DAVID D. STEWART, M.D.,

OF PHILADELPHIA;

PROFESSOR OF DISEASES OF THE STOMACH AND INTESTINES IN THE PHILADELPHIA POLYCLINIC; VISITING PHYSICIAN TO THE EPISCOPAL HOSPITAL, ETC.;

AND

ALOYSIUS O. J. KELLY, M.D.,

OF PHILADELPHIA;

ADJUNCT PROFESSOR OF PATHOLOGY IN THE PHILADELPHIA POLYCLINIC; VISITING PHYSICIAN TO ST. MARY'S AND ST. AGNES' HOSPITALS.

(Continued from page 198.)

The mode of infection in these cases is a most interesting problem, and has long been a fruitful source of discussion. In many cases it is exceedingly obscure, and cannot be removed from the realms of pure conjecture. Three possibilities only suggest themselves: (1) Hematogenic infection. (2) Ascending infection from the lower urinary tract, either by means of the urine, through the spread of the disease along the ureter, or by the conveyance of the virus through the lymphatics. (3) Extension from similar processes of neighboring organs. The latter, if it occurs at all, must be a very rare mode of infection. The kidney notably is exempt from participation in the disease of neighboring structures, as of the vertebræ, adrenals, etc. The capsule probably acts as a protecting membrane; witness the non-implication of the kidneys in tuberculosis of the suprarenal bodies, even when the latter, as it sometimes does, gives rise to a perinephritic abscess. The mode of infection must, therefore, be hematogenic, or the kidney must become implicated by an extension of the process from below upward. There is clear evidence in support of both views. We thus recognize that the caseous variety of tuberculosis of the kidney may either be a primary or a secondary affection, and that there may occur both an ascend-

ing and a descending tuberculous infection of the genito-urinary tract; and, further, we must allow that various parts of the tract may be simultaneously involved. There can be no doubt that in the case reported by us the infection was hematogenic, and this also is doubtless the most frequent mode of infection in the ordinary primary caseous or local tuberculosis of the kidney, there subsequently ensuing a descending infection of other parts of the lower genito-urinary tract. It thus appears evident that a primary tuberculosis of the kidney, similarly as primary tuberculosis of the bones and lymph-glands, may occur by hematogenic infection without any demonstrable tuberculous lesion in any other part of the body. Of course, one can hardly exclude the possible presence of a small tuberculous focus which may have eluded detection. The interesting question under these circumstances is, In what manner do the bacilli gain access to the body and enter the blood-vessels? One naturally has recourse to the experiments which serve to prove that the bacilli may enter the body without setting up lesions at the port of entry. We further recall the symptomless course of many unsuspected cases of tuberculosis of various structures—of the tonsils, bronchial and cervical lymphatic glands. Infection of the latter, it appears from some recent investigations, may occur by means of totally latent tuberculosis of the teeth. Again, the tubercle bacilli have been demonstrated in the renal glomeruli before any cellular exudate has occurred. But, despite various facts and theories, the mode of infection of some cases of primary tuberculosis, not only of the kidney, but also of other organs, is exceedingly obscure. At times the question is impossible of solution.

While from the appearances of a kidney, removed either *post-mortem* or by operation, it frequently is relatively easy to determine the route of infection, in a not inconsiderable proportion of cases this is a matter of very great difficulty, and is at times impossible. Disseminated or secondary miliary tuberculosis, and the primary form of miliary tuberculosis such as we report, are readily recognized as instances of hematogenic infection. When, however, more or less of the entire urogenital tract is affected, it requires a careful consideration of the relative stages of the various lesions found at the more remote points of the disease to determine the route of infection; to determine whether or not the general implication is an instance of descending or of ascending infection; in the latter case, of course, we can but speak of a secondary involvement of the kidney. A more advanced stage of the disease about the trigone or fundus of the bladder, for instance, and relatively little implication of the kidney, and that limited to the

pelvis or papillæ, would be clear evidence of an ascending infection. Again, extensive destruction of the kidney, more especially toward the cortex, with some slight involvement of the ureter and a healthy bladder, is sufficiently characteristic of the descending variety of the infection. Attention might here be drawn to the fact that whereas a few years ago the generally accepted opinion was that the kidney involvement in caseous tuberculosis was usually an instance of ascending infection from the lower urogenital tract, the trend of recent opinion is that the primary focus is commonly situated in the kidney, the other organs of the genito-urinary system becoming secondarily involved.

Not rarely both kidneys are affected, though one is generally found to be in a more advanced state of disease than the other. This bilateral implication may be the result of simultaneous infection, or, as is most probable, usually the second kidney has become infected from the first by a descending and subsequent infection. The tuberculous disease of one kidney gives rise to a descending infection of its ureter, and finally the bladder, the mucous membrane of which, especially that about the trigone and fundus, becomes the seat of miliary tubercles or becomes infiltrated or ulcerated. The ureter of the healthy kidney becomes diseased and its mucous membrane thickened. This results in obstruction of its lumen and consequent hydronephrosis, which shortly becomes purulent. Thus, the tuberculous infection is presented to the pelvis of the healthy kidney, which soon succumbs to the attacks of the morbid agents. It is believed also that an urethral obstruction occasioning retention of urine may result in such disease of the second kidney, and this sometimes without affecting the bladder, the mucous membrane of which is notably resistant to the injurious influences of disease germs.

Primary tuberculosis of the kidney may occur at any age, but is more frequent in adult life and old age. Hamill, who has recently made a very exhaustive study of the disease as it appears in early life, and who has reported a case in one of the youngest patients on record—a child aged seven months¹—remarks that “it is relatively uncommon in childhood and exceedingly rare in infancy.” In the young the conditions probably are not identical with those found in later life. It appears that more males are affected than females. The etiologic factors are those of tuberculosis in general.

As already remarked, disseminated miliary tuberculosis of the kidney may not and usually does not give rise to any special symptoms, being but part of a general process. It is also true that primary miliary

¹ *International Medical Magazine*, 1896.

tuberculosis, as well as the ordinary variety of primary or caseous tuberculosis of the kidney, may persist for a considerable time without exhibiting any clinical manifestations of its presence. Rosenstein is authority for the statement that symptoms develop only when the mucous membrane of the pelvis and calices or ureter become the seat of inflammation, or when the caseous tubercles rupture into the pelvis; but, as evidenced by the case reported by us, even the implication of the mucous membrane of the pelvis may not give rise to any obtrusive indications. Rosenstein further asserts that the initial symptom of all cases (at least in all of the considerable number observed by him) was dysuria.

Laroche, a recent observer, feels justified in dividing all cases, according to their initial manifestations, into three classes—those which commence with hematuria, those which commence with pain, and those which commence with vesical symptoms; but, as further instanced by the case reported by us and by others, the condition may not be suspected until the accidental discovery of pus in the urine, during a careful examination of the renal secretion, suggests to the examiner the wisdom of examining the sediment for tubercle bacilli.

The symptoms which, developing, attract the attention of the patient usually are, in the beginning, either lumbar pain, turbid urine, hematuria, or, what the patient is more likely to observe, frequent and painful urination and hematuria. Any of these may occur alone, or there may be various combinations. Guyon was wont to refer to pus in the urine and frequent and painful micturition as the common symptomatic triad of urinary tuberculosis.

Lumbar pain may alone be present, and may either be spontaneous or provoked. The spontaneous pain may be very slight, amounting only to a so-called loin tire, or it may be very severe. It usually is limited to the lumbar region; and is present on, or at least is more severe on, the diseased side. It is not ameliorated by repose nor aggravated by movement. Sometimes the pain is lancinating, and even when so it may be confined to the lumbar region, or it may exhibit radiations in the direction of the ureter or into the testicle. Again, veritable crises appear at irregular intervals. They are of variable intensity and duration, and usually develop without manifest cause. They much resemble attacks of nephritic colic. The pain is generally aggravated by pressure—that is, by an examination of the renal region; but pain provoked only by an examination, at other times being absent, must be a rare indication of primary tuberculosis of the kidney.

Vesical and urinary symptoms have for a long time been known to accompany various diseases of the

kidney, despite the integrity of the bladder, and in primary tuberculosis of the kidney they are common. Frequent and painful micturition are common initial symptoms. At times pain may be intense, and situated at the neck of the bladder and accompanied by aggravated vesical tenesmus. Frequent urination, by night as well as by day, is often the first obtrusive symptom, even before the appearance of pus or blood appreciable to the eye in the urine. It often co-exists without painful urination, so that the patient may complain only of the mere annoyance of the great frequency of the act of urinating.

The presence of blood in the urine, often only to be detected microscopically, is probably the most frequent initial symptom, and may be present for a long time without any other manifestation of the disorder. Its production is readily accounted for by the fact that the bacilli, gaining access to the glomeruli, there set up a congestion which speedily progresses to rupture of the blood-vessels and consequent appearance of blood in the urine. It not only occurs early, but may continue also during all stages of the affection. Hematuria varies much in amount, and usually occurs without provocation—that is, it develops as it also ceases—spontaneously. The time of its occurrence and its amount are uninfluenced by movement or repose. It may be accompanied by severe pain, but even when profuse it is generally painless.

An examination of the kidney region often affords important diagnostic data in a suspected case. A kidney increased in size and painful is valuable evidence of the condition. The kidney unaffected with the tuberculous process may be enlarged from compensatory hypertrophy, but it is not painful. On percussion the area of kidney dulness is found to be enlarged; to facilitate the limitation of this area the employment of auscultatory percussion by means of the binaural stethoscope or the phonendoscope may be of value. Careful and thorough bimanual palpation alone will commonly enable us to distinguish enlargement, especially when the right kidney is involved. A kidney increased in size and painful may be observed very early in the disease. Later, there may be bulging of the loin and a tumor in the abdomen. The latter, depending upon the state of the pathologic processes in the kidney, varies much in size and other characteristics. The general conformation of the kidney is usually retained, but the tumor-mass may be very voluminous from a pyonephrosis consequent upon an obstruction of the ureter. If the several renal cavities reach the surface of the organ, the tumor-mass may feel bosselated. It may be resistant to pressure—that is, it may be hard or firm—or it may be elastic or fluc-

tuating. It may be so exquisitely painful to pressure that a satisfactory examination cannot be accomplished without the use of an anesthetic, which is usually contraindicated.

The most important symptom of the disease is the specific alteration of the urine. The characteristics of the urine are the reflection of the renal condition, and when a direct examination of the organ leads to indefinite results an investigation of its secretion furnishes positive signs. The urine may vary in amount. In the initial stages polyuria with frequent urination may be the sole symptom. Later, the quantity of urine depends in a great measure upon the state of the renal parenchyma. With destruction of the secretory tissue the urine diminishes in amount, but with an associated cirrhosis of the other kidney polyuria would be usual. The polyuria frequently is intermittent, and commonly is excessive after the removal of an obstructing particle from the ureter. The specific gravity of the urine generally is normal or somewhat subnormal. With marked polyuria it is of course very low. The reaction is acid. The urine is usually turbid when voided, but not infrequently is clear, and this sometimes is said to be especially the case during the painful crises, following which marked turbidity supervenes. Again, after turbid urine has been voided for a while it may suddenly clear and remain without sediment for some time. A sediment sometimes is deposited immediately upon the urine being voided; again, it does not deposit for some little time. This consists of pus, blood, epithelium (occasionally casts), connective tissue, elastic fibers, and detritus. Cholesterin plates, crystals of calcium carbonate, phosphate, and oxalate are sometimes found. The quantity of pus is variable, as also is the albumin, which, with the presence of pus, is of course always found, and in amount depends upon the pus and blood. With parenchymatous disease of either the tuberculous or the other kidney the percentage of albumin increases. Tubercle bacilli are always demonstrable in the sediment, at some time in the course of the case.

As the disease progresses constitutional symptoms develop, but it is remarkable how extensive the kidney disease may become before they manifest themselves. The patient, from the first somewhat pallid, with perhaps little loss in flesh, gradually grows weak and finally emaciated. There is present anorexia, with increasing anemia, and an evening rise in temperature. The patient eventually passes into a condition of decided cachexia, and death may thus occur without extension of the tuberculous process beyond the genito-urinary tract.

As illustrating how insidious in onset and symptomless in at least a portion of its course tuberculosis

of the kidney may be, the following case, occurring in private practice, is of considerable interest. In this, with the absence of the commonly observed frequent urination and hematuria (at least macroscopic), the first indication of any departure from health was the accidental discovery of pyuria.

W. R. S., male, aged thirty years, a dentist; weight, 145 pounds; family history good. Although he never had been robust, his health had always been fair. He was subject to "colds." He consulted Dr. Stewart for the first time during October, 1896, for the purpose of ascertaining the cause of the presence of albumin in his urine. Two and one-half years before he had taken out an insurance policy in a prominent company. At that time no abnormalities of the urine were noted. Six months before he came under observation he was insured in another and less prominent company. At this time, also, an examination of his urine was made, although by an examiner of less note than the first one. Shortly before consulting Dr. Stewart the patient desired to increase the amount of his life insurance. He was told by the examiner for the company first referred to that it would be impossible at that time, as his urine contained albumin.

A specimen of urine voided for examination was found to contain considerable pus, with albumin in amount only to be accounted for by the presence of the pus. The patient then recalled that for several months past the urine had commonly been turbid on voiding. To this he had not before attached significance. The patient's general health was good. In appearance, although well nourished, he was somewhat pallid. An examination of his blood disclosed a minor grade of anemia—hemoglobin, 65-per-cent.; erythrocytes, 4,000,000; no leucocytosis. There had been no loss of flesh, and his health, save for occasional slight attacks of bronchitis in winter, had always been good. Some five years previously he had had more or less bladder irritability, and this had persisted as a quite constant symptom for perhaps two years. The indications pointed to a mild chronic cystitis, for the development of which he could offer no explanation. He had not had gonorrhea. The bladder trouble, which at no time had been more than slight, had entirely disappeared about three years before he came under observation, by the use for a short time of suppositories consisting of belladonna, iodoform, and cocain. His health since had been very good. He had taken a great deal of outdoor exercise, chiefly a wheel. He was absolutely symptomless when seen for the first time for his present ailment. Irritability of the bladder was entirely absent, and had been persistently so for the past three years. He never rose at night to urinate, and rarely passed water over three times during the twenty-four hours. Hematuria had never occurred to his knowledge. The testicles and their appendages were to all appearances normal. There was no tenderness about the neck or other palpable portions of the bladder. The kidneys were not palpable, and tenderness in the region of their location,

even on firm pressure, was absent. The lungs and heart were normal.

The case was regarded as one of probable tuberculosis of the kidney, and a search in the urine for the tubercle bacilli was at once instituted. As a matter of routine, specimens of the urine were examined systematically in Dr. Stewart's laboratory, both by himself and Dr. A. A. Ghriskey, twice weekly, for seven weeks before tubercle bacilli were found. They were at last discovered by Dr. Ghriskey after their detection had been almost despaired of. At the end of this time, in the first specimen prepared, in one field only, a very large number were found in good-sized clumps, and others isolated. No other fields contained them. Evidently, those encountered were from a small shred of tubercle which had escaped into the urine.

The amount of urine voided, measured during several days at intervals, was found to run constantly between 1200 and 1500 c.c. Although turbid on voiding, it always became clear on standing. Specimens of the day's urine deposited a considerable sediment, consisting solely of pus. That passed on arising in the morning commonly contained pus in much less amount. The urine was always of acid reaction, of normal color and specific gravity, and the twenty-four hours' output habitually showed normal urea for body-weight and diet. Albumin was present only proportionately to the amount of pus, from which it was evidently derived. Microscopically, pus-cells abounded. Erythrocytes and bladder epithelium were not noted. Casts, in the many examinations made, were never encountered.

Thermometric observations, made twice daily in this case for over a month, showed no afternoon or evening rise of more than half a degree.

A diagnosis of presumed tuberculosis of the pelvis of the kidney was made and the patient kept under steady observation. During this time, as narrated, a search for tubercle bacilli was being made. The treatment consisted of a nutritious diet, fresh air, and a good deal of rest in recumbency throughout the day. Guaiacol benzoinate was employed internally, although not with any expectancy of benefit. Rather large doses were at first taken, resulting in mild toxic symptoms, the chief of which was a tendency to persistent chilliness, which ceased on discontinuance of the remedy. During the time it was being taken in full doses, on undue exposure to wet and cold, a chill occurred, followed by soreness in the region of the left kidney. When seen, the second day after this was experienced, there had been some diminution in the amount of urine voided (the quantity at this time not being measured). There was also a perceptible though slight fulness

evident in the loin anteriorly and laterally. The loin was somewhat tender on pressure. This was the only indication of hydronephrosis which had ever occurred. It was not repeated while he was under observation. Drinking freely of hot lythia water, and the employment of dry cups, followed by a poultice, caused a prompt subsidence of the symptoms.

The patient was under observation about three months, and, although now no longer under Dr. Stewart's care, is occasionally seen. Immediately on finding the tubercle bacilli in the urine the patient was urged to submit to a cystoscopic examination. The intention was to make an inspection of the bladder and to attempt catheterization of the ureters, in order to determine if the process, as was supposed, was limited to one kidney. If this suspicion was confirmed surgical interference was contemplated. But to the cystoscopic examination the patient would not consent, although the necessity of it was persistently laid before him, he being given to understand that no remedy could be curative of his condition. For this reason he consulted another physician, who held out to him greater promise of relief by drugs.

In this case the indications strongly pointed to a tuberculous pyelitis of one kidney, presumably the left. The ailment was probably of recent origin. It was unaccompanied by any indication of genito-urinary implication. The bladder symptoms, which were present several years previously, were of themselves highly suggestive, but should not be accorded undue weight, as they were not accompanied by any signs of renal derangement, the latter not developing until three years after the subsidence of the symptoms of vesical irritation. During this time the man had enjoyed good general health, and two examinations of his urine for life insurance had failed to disclose any indications of abnormality.

The diagnosis of primary tuberculosis of the kidney, particularly in the early stages, is frequently a matter of the greatest difficulty. The diagnosis may be at times most positive and again most uncertain. As in the two cases reported by us, the disorder may develop entirely without subjective symptoms. In the first case the tuberculous disease became engrafted upon a kidney the seat of chronic inflammation, and it was the presence of pus alone which suggested the wisdom of examining the sediment for tubercle bacilli. In the second case the first indication of abnormality was the accidental discovery of albumin in the urine when the patient desired an increase in his life insurance. The albumin was found dependent upon pus, and this again led to the examination of the sediment for tubercle bacilli. In this case it was only the persistent and frequently repeated examina-

tions for a period of almost two months which were finally rewarded by their detection. We cannot, therefore, in the diagnosis, too strongly accentuate the suggestiveness of the presence of pus—even in very small amount—in acid urine. The negative result of the examination of the urinary sediment for bacilli is not evidence of freedom from tuberculous disease. The examinations must be frequently and persistently made. The positive evidence only is of certain diagnostic importance. We confidently believe that the systematic, careful, persistent, and frequently repeated examination of the sediment of urine containing pus, even in small (microscopic) amounts, would more often permit of the recognition of the class of cases to which we allude. Rarely the urine may not be acid. It may have been rendered alkaline by some complicating condition, such as a cystitis induced by the employment of an unclean catheter. In a case of Dr. Stewart's, in which both kidneys were involved in the tuberculous process and were converted into mere pus-sacs, the urine had steadily remained acid until a catheterization, subsequent to operation on one of the kidneys, induced a cystitis, with ammoniacal fermentation.

The absolutely diagnostic sign of renal tuberculosis is the discovery of the tubercle bacillus. Care must be taken not to confound the smegma bacillus with the tubercle bacillus—an error which has led to the removal of a kidney the subject of calculus only, but presumably the seat of tuberculosis. Although the staining peculiarities of these bacilli are in many respects alike, the arrangement of tubercle bacilli into masses and groups (and this especially occurs in tuberculosis of the urogenital tract), is quite distinctive. The differential characteristics existing between the smegma and the tubercle bacilli have been especially studied by Grethe and von Leyden. The smegma bacilli are more readily decolorized by acidulated alcohol, losing their stain in two minutes, while tubercle bacilli do not. The smegma bacilli do not stain by Gram's method; the tubercle bacilli do. Grethe advises staining a cover-slip preparation first with carbol fuchsin, in the ordinary manner, and then with a concentrated alcoholic solution of methylene-blue. The smegma bacillus is thus stained blue, and is in marked contrast to the tubercle bacillus, the red color of which is not interfered with. When, after persistent search, the tubercle bacilli cannot be detected in the sediment, small flakes of tissue being especially looked for as most likely to contain them, the question of diagnosis may be settled by injecting some of the sediment into the anterior chamber of the eye or into the peritoneal or pleural cavity of a rabbit or guinea-pig. Of less value is gelatin or other plate-cultures from the

pus. The discovery of connective tissue and elastic fibers in the sediment merits careful consideration. While not diagnostic of tuberculous disease of the kidney, their presence still points to some extensive destructive disease in the kidney, and this is usually tuberculous or dependent upon a calculus. The suggestiveness of these is greatly increased when they are associated with degenerated particles of tubercles, which are so common in the urine and which generally appear as granular, amorphous masses. The diagnosis is further confirmed should there be present hematuria and indications of enlarged and painful kidney, lumbar pain, and vesicle irritability.

Tuberculous kidney converted into a pus-sac.

The evening elevation of temperature, as insisted upon by Rosenstein, cannot be so distinctive and essential a symptom as he would have us believe. In our second case the evening rise did not amount to more than the normal elevation, and in the first case the elevation which occurred might be regarded as dependent upon the other conditions present. However, an evening rise of temperature in association with acid urine containing pus is very suspicious of tuberculous disease. Confirming one's apprehension of a possible tuberculous disorder of the kidney is the discovery of similar disease of other parts of the genito-urinary system, as of the testicle, epididymis, vas deferens, seminal vesicles, prostate, bladder, ureter, and, in the female, the Fallopian tubes.

The presence of persistent lumbar pain, pyuria,

hematuria, and vesical symptoms all call for a careful investigation of the kidney. The impartial observer will hardly mistake the lumbar pain for a lumbago; nor should a pyuria with vesical symptoms be too long referred to a catarrh of the bladder. Frequent micturition alone or accompanied by hematuria, but without lumbar pain or other symptoms, is in itself very suspicious.

The distinction between calculary pyelitis or pyonephrosis and tuberculous disease, is at times a matter of some difficulty. Vesical irritability is common to both conditions, but the lumbar pain of calculus is usually of a duller, much more persistent character, aggravated by motion, and associated with attacks of renal colic in which the pain is agonizing, and radiates into the lower genitalia and into the thigh. When such attacks accompany tuberculous disease, they are generally much less intense. Hematuria is more severe in renal stone, and is often induced by exertion. Enlargement of the kidney is not so common, and only occurs when the stone becomes impacted in the pelvis or in the ureter, and this is usually late in the course of the disease. There then ensues a hydro- or pyonephrosis. The urine usually is highly acid in calculary disease, with a specific gravity normal or above; it usually contains, if the calculus be of uric-acid formation, an abundance of crystals of the same; if of calcium oxalate, similar crystals are likely to be present in excess. Casts are less frequent than in tuberculous disease, and the bacilli are, of course, not encountered. While good general health may be maintained for a long time despite the tuberculous involvement of the kidney, still the patient is more apt to show deterioration sooner with tuberculous disease than he is with renal calculus. For an exceedingly long time between the attacks of renal colic the patient's general health is excellent. In tuberculous disease, not infrequently some emaciation, anemia, night-sweats, loss of appetite, etc., develop rather early. The symptoms are sometimes indicative of vesical calculus, but from this the employment of a sound or the cystoscopic examination of the bladder readily differentiates. Both the renal and the vesical calculi may further be excluded by the results of a Röntgen skiagraph. Malignant disease of the kidney usually is easily eliminated from the possibilities. Frequent urination and hematuria are the only urinary symptoms common to both conditions, but they may be absent in malignant disease, and, if present, are apt to be prominent symptoms. The tumor generally grows very rapidly, renders the kidney firm to the touch, bosselated, and may lead to distortion of its shape. Sarcoma is the most frequent tumor, and it is in children that confusion is most likely to arise.

In all cases, and especially in women, in which such examination is now a matter of comparative ease, by the employment of the improved methods of Howard Kelly, a cystoscopic inspection of the bladder, and especially of the ureteral orifices, should early be carried out. In women, in addition, catheterization of the ureters is a matter of little or no difficulty, and may be essential to determine, by an examination of the urine from each kidney, the question of single or double involvement. Meyer holds that in a suspected case the use of the cystoscope will determine the diagnosis, even though repeated search in the urine for tubercle bacilli has been resultless.

Meyer¹ states that with involvement of but one kidney, by the cystoscope a permanently normal vesical mucous surface is seen with a single healthy ureteral opening. The orifice of the other ureter, however, is injected. "A number of circumscribed, clearly defined, inflamed areas of mucous membrane can be seen between it and the slightly hyperemic trigonum, leaving the interposed tissue unchanged in appearance." No other disease of the kidney or bladder presents a similar cystoscopic appearance, in Meyer's opinion.

The case, however, may be encountered before such a cystoscopic picture is evident. In any event, in addition to cystoscopic examination, catheterization of both ureters, when possible, should be accomplished to obtain separate specimens of urine. In its performance the chances of infection of the yet healthy kidney must be thought of and precautions taken to minimize the chances of such an accident.

Catheterization of the ureters in the male, unfortunately, is attended with great difficulty, and has been accomplished by few, either in this country or abroad. By these it has been done sufficiently often to indicate that, although not easy of accomplishment, it is at least, in experienced hands, practicable.

The prognosis in the vast majority of cases without operative interference is absolutely fatal. One can think of the possibility of the disease being limited to one kidney, the substance of which wastes and finally becomes the seat of "clinical but not anatomic recovery," while the other kidney remains intact. But such a possibility is very remote. The disease lasts for from six months to two or three years, as a rule, though instances of cases of much longer duration have been recorded. Death follows from cachexia, or it may be due rarely to uremia, from associated chronic nephritis, as in the case related by us.

The treatment of primary tuberculosis of the kidney, of whatever variety, is distinctly surgical; the

¹ THE MEDICAL NEWS, March 1, 1896, and May 1, 1897.

employment of tuberculin, the recently vaunted proto-nucleins, and drugs, such as guaiacol benzoinate, being without permanent benefit.

The surgical management of the case will not be here considered. Of the greatest practical importance is it, by careful hygienic and medical means, to place the patient, prior to operation, in as favorable a physical condition as possible, that any latent tuberculous process other than that in the kidney, such as might exist in the lungs, be not subsequently stimulated into activity through the depression attending operation.

Theoretically, apart from the ability to directly reach the morbid process and effect its removal, operation, the immediate effects of which are well understood, may not be without benefit on tuberculous lesions elsewhere, in a manner similar to that in which cure often results from mere incision in cases of tuberculous peritonitis. The most plausible explanation of the remarkable results obtained by mere exploratory celiotomy in cases of tuberculous peritonitis is that of Kischenski,¹ who regards the benefit or cure resulting due to the invariable post-operative leucocytosis. The beneficial effects in peritoneal tuberculosis, although in all probability so resulting, cannot be expected to repeat themselves in the same degree in tuberculous lesions elsewhere, for certain reasons (see, as to this, a paper by Vaughan, "Yeast Nucleinic Acid in Tuberculosis," *THE MEDICAL NEWS*, March 6, 1897, p. 300); yet much may be expected if the system is well fortified, prior and subsequent to operation, by supportive treatment. In these cases the free administration of the preparations of nuclein, and especially, as advised by Vaughan for use in general tuberculosis, of yeast nucleinic acid, may be of considerable advantage.

CLINICAL MEMORANDUM.

REPORT OF TWO CASES OF SYPHILIS, WITH REMARKS RELATIVE TO PTYALISM.

By C. TRAVIS DRENNEN, M.D.,
OF HOT SPRINGS, ARK.

IN ascertaining the proper dose of mercury for syphilitic subjects one necessarily is governed by certain signs and symptoms, and one of these, which is almost universally watched for at the present day, is sensitiveness of the gums. The majority of general practitioners and syphilographers begin the treatment with small doses and gradually increase the amount of the drug each day, directing the patient to close the jaws and press the teeth firmly together at intervals, and when the slightest sensation of tenderness or soreness makes its appearance they desist from increasing the dose, as the point of tolerance

has been reached, beyond which it will be dangerous to go. I desire to state as a result of long experience and observation, and in the face of recognized authority, that this soreness of the gums is a poor guide in the management of these cases, which fact the following reports will demonstrate:

A gambler, twenty-four years of age, a native of New York, came to me during the winter of 1895 suffering from tertiary syphilis. Four years before he had had a chancre, which was followed by the appearance of buboes in each groin, the left one suppurating. On this account he was confined to bed for nine weeks, during which time he was much troubled with nocturnal headaches, rheumatic pains, and fever, but there was no general eruption. He was treated for chancroids, but received no other treatment whatever. During December, 1895, after a night's debauch, a lesion made its appearance upon the glans penis. He at once consulted a surgeon, who proceeded without delay to thoroughly cauterize it, but the results were not such as he anticipated, inasmuch as the ulcer immediately became phagedenic, and in about ten days no less than two-thirds of the glans penis had been destroyed. On the second or third day after this lesion made its appearance, others appeared on different parts of the body, ranging in size from that of a one-cent piece to that of a silver dollar and even larger. These lesions were of the character of bullæ, and were followed in a few days by deep and ugly ulcers. He was at once put upon antisyphilitic treatment, but finding himself rapidly growing worse he left his home and came to the Hot Springs, and it was upon the 5th of January that I first saw him.

At that time he was markedly anemic, and was absolutely covered with ulcerations, some of them being an inch in diameter, and even larger. There were several large ulcers in the mouth and throat, and it was with much difficulty that he could swallow, his food having been limited during the previous two weeks to liquids. His weight was 113 pounds, as compared with his former weight of 138.

Inunctions of one-eighth of an ounce of mercurial ointment were employed for eight days and he was given thirty drops of the syrup of iodid of iron, well diluted, one hour after meals, and beef, chicken, or mutton broth, and as much sweet milk as he could take, four times daily. The throat was treated with antiseptics and the ulcers touched every other day with a twenty-grain solution of nitrate of silver, while an ointment containing ten grains of aristol was applied to the ulcers on the body. By the end of the first week desire for food had returned, and with it ability to sleep, which heretofore had been obtained by the use of hypnotics. The mercury was continued with most satisfactory results, for on the twenty-second day after his arrival only two lesions remained unhealed, the one upon the penis and one upon the forehead. His weight at that time was 128 pounds and he seemed in a fair way to recover. He was then placed upon a solution of iodid of potassium for ten days, in increasing doses, which he did not tolerate very well, and he was again returned to the use of iron and mercury. After

¹ *Centralblatt für Chirurgie*, 1893.

the second injection he became despondent and hysterical and talked of suicide. An intense soreness, with much swelling manifested itself in the esophagus, and it was with much difficulty that he could swallow at all. On the next day he was given another injection, which seemingly intensified all of the symptoms to an alarming degree, and at the same time complete anesthesia of both arms and legs from the elbows and knees down occurred. So complete was this anesthesia that he experienced no pain whatever when I ran a large needle not only into but entirely through the gastrocnemius muscle of the left leg. He was then directed to take vapor baths and to drink large quantities of water, and further medication was discontinued. After ten days sensation again was about normal. The succeeding history of the patient is uninteresting, as he recovered under tonic treatment without further difficulty. The point to be brought out here is, that during all this time never for a single moment were there any signs of salivation or of tenderness of the gums. This case is only one of many which I could cite as bearing upon this feature.

The second case presents an entirely different picture; it occurred in the person of a young married woman, twenty-two years of age, the mother of a child four years old. Three months after the birth of this child the patient contracted syphilis from her husband. She had the initial lesion, which was followed by non-suppurating inguinal adenitis, slight eruptions, and sore throat. Her husband permitted her to remain in this condition during nine months without treatment. She was thoroughly wretched, being crippled from the effects of rheumatism, and suffering intensely from sore throat all the time, her weight decreasing from 130 to 94 pounds. Finally, she was placed under treatment at her home in Ohio for a period of about four months, but failing to improve, was sent to the Hot Springs, where she took mercury and the iodids, so she states, during three months, but to no purpose except that her condition became worse. Salivation was invariably produced after a few days' use of mercury, and new ulcerations made their appearance in the mouth and throat. She then fell into the hands of a throat specialist, who employed local treatment and tonics, and with fair results, for about two months later she returned to her old home, but after remaining there two weeks the lesions developed again. She immediately came back to the Hot Springs and resumed treatment with the physician who had treated her before, but the ulcerations increased and finally were followed by a stricture of the esophagus which required dilatation. During this time her physician made a trial of practically all tonics and antisyphilitic remedies, and stated to me that the patient could not tolerate mercury in sufficient quantities to do her any good. She had had her teeth repeatedly attended to by a competent dentist, but the salivation resulting from the exhibition of mercury was so pronounced that she could neither eat solid food nor could she sleep. She remained in this condition during one year and a half, and then, on April 27, 1897, came under my care.

Her weight at that time was 108 pounds. She did not

appear to be anemic, but tired easily upon exertion, had a poor appetite, and was constipated. The heart, lungs, kidneys were normal. The spleen was slightly enlarged. There was one ulcer upon the left tonsil, one upon the tongue, and a third upon the lips, while the mouth and throat were covered with scars. An examination of the blood showed a reduction of hemoglobin to 35 per cent. and a diminution of red blood-corpuscles to less than two-thirds the normal number.

An antiseptic mouth wash was prescribed for frequent use, and the ulcers were touched every second day with a twenty-grain-to-the-ounce nitrate of silver solution. The blood was examined every fifth day. Ten days after the beginning of this treatment another ulcer made its appearance low down in the pharynx, and the others showed no improvement. The amount of hemoglobin had been reduced to 20 per cent., and the woman's strength was so impaired that it was only with difficulty that she could walk. During this time her gums were so sensitive that they bled freely whenever she attempted to eat. She was then given sixteen drops of a preparation of gold and mercury, one hour after each meal, with one tablespoonful of a solution of peptonate of iron and manganese. The latter preparation was discontinued on the second day, as it gave rise to severe headaches, and the mercurial preparation was increased to twenty drops thrice daily, but on the fourth day she again became intensely salivated. I then treated the gums with a 4-per cent. solution of cocaine, and with a strong, stiff tooth-brush literally tore them to pieces, afterward allowing the blood to flow freely. The tissues were then treated with an antiseptic solution, followed by alcohol. This treatment was repeated daily, and the mercurial solution, instead of being discontinued, was increased in quantity until she was taking thirty-five drops a day.

On May 12th the hemoglobin registered 25 per cent., the red corpuscles being as before. On May 17th the hemoglobin still registered 25 per cent., but on the 22d it was 30 per cent., on the 27th 35 per cent., on June 1st, 40 per cent., June 6th, 45 per cent., June 11th, 55 per cent., June 21st, 70 per cent., June 26th, 70 per cent., and on July 1st, 80 per cent. At the latter date the number of red blood-corpuscles was normal, the patient's weight had increased to 131 pounds, and she felt better than for several years, in fact, since the beginning of the disease.

These cases are of interest on account of their wide dissimilarity. The first patient took mercury, with excellent results up to a certain time, when poisoning by the drug occurred and very nearly proved fatal. At no time did signs of pyalism become evident nor did the gums become sensitive. The second patient, on the contrary, became salivated whenever mercury in even small doses was given, yet she was made to take large quantities of the drug with most satisfactory results. There are few patients who will use a brush on tender gums with sufficient force to be of service, and I make it a rule, no matter if the teeth and gums appear to be in perfect condition, that every syphilitic patient must visit a dentist and have the teeth thoroughly overhauled and then, in my

presence, scrub and brush the gums vigorously. I feel assured that with these precautions, and watching carefully the condition of the blood, we have little to fear in giving even very large doses of mercury.

MEDICAL PROGRESS.

Spontaneous Rupture of the Aorta.—AMES AND TOWNSEND report in the *Maryland Med. Jour.*, July 3, 1897, a case of spontaneous rupture of the aorta without aneurism, occurring in a man aged seventy-five, due to a crack in a calcareous plate in the aortic wall not far from the valves. From the meager history of the case obtainable, it appeared that the man died suddenly while at work. Some hundred such cases have at one time and another been reported, and though the subject has little clinical importance, it is interesting to notice the points which a study of these published cases brings out. It is probable that an examination of the many cases of heart failure and sudden death would show that many of them are really cases of ruptured aorta, and that this accident is by no means so rare as has generally been supposed.

Two-thirds or more of all cases occur in men, and almost as large a proportion in the ages between thirty and sixty. Probably in every instance the aorta is diseased. This has been denied by some, but reason and the cases reported both agree in sustaining this theory. Granted a diseased vessel, and most likely a hypertrophied heart as well, it is evident that a strain, such as produced by a fit of anger, or an attack of vomiting, will increase tension beyond the power of the weakened aorta to withstand it. In 60 per cent. of the cases the rupture is near the heart, while in 20 per cent. it is in the curved portion of the vessel. Rupture of the abdominal aorta is most rare. The explanation of these statements was long ago given by Rokitsky and Broca, who insisted that the recoil force of the column of blood in the aorta might be sufficient to tear up the intima, if diseased, and sometimes the media as well, just above the aortic valve segments.

The most constant symptom is pain, severe and tearing in character and located in the chest, though radiating to the neck, shoulders, or abdomen. Of other symptoms, dyspnea, collapse, feeble, irregular pulse, vomiting, giddiness, chilly sensations, cough, drowsiness, and hemoptysis are occasionally noted.

The Etiology and Pathology of Acute Peritonitis.—FLEXNER publishes, in the *Maryland Med. Jour.*, June 25, 1897, an analysis of 101 cases of acute peritonitis, which throws a little additional light on this still too obscure subject. There is a great probability that the capacity of resistance of the normal peritoneum is closely associated with the preservation of the integrity of the normal peritoneal covering. We may disregard for the present, as not yet proven, the idea of a non-infectious or chemical form of peritonitis.

An examination of these 101 cases of acute peritonitis from the autopsy records of Johns Hopkins Hospital, in which bacteriologic examinations were carried out, shows that these cases may be divided in three groups:

1. **Primary or Idiopathic Peritonitis.**—In these the infectious agent did not enter from without as a result of a surgical operation, or from within through the medium of a diseased viscus. There were 12 of these cases, and the predominating pathogenic bacteria were pyogenic strepto- and staphylococci. All but 1 were mono-infectious.

2. **Exogenous Peritonitis.**—These were all cases of post-operative peritonitis, in which the germs did not enter from a diseased viscus but were introduced at the time of operation. There were 33 cases of this class, 25 of which were mono-infectious, and 8 polyinfectious. The predominating organisms here were also the cocci, but bacilli were more common than in class 1.

3. **Endogenous Peritonitis.**—In these cases the infection comes from the intestine. There were 56 in all, 23 being mono-infectious and 33 polyinfectious. The predominating micro-organisms were the bacillus coli communis and the streptococcus pyogenes. The former occurred in 43 of the 56 cases, but it was present alone only 8 times. The latter was present 37 times, but only 7 times alone. There was also a much greater variety of other bacteria present than was the case in the other two classes.

Sarcoma from an Irritated Mole.—GRANT mentions in the *Intercolonial Med. Jour. of Australasia*, May 20, 1897, an instance of sarcoma developing from a mole as a result of thrice-repeated injury. The patient, a healthy man of twenty-seven, had had a black mole on his right arm since birth. At the age of twenty-four it was torn by the horn of a sheep, but healed rapidly. A little later it was again injured, and increased to the size of the finger tip. After a third bruise, received eighteen months after the first injury, it was still larger, and several secondary spots had appeared in the vicinity. All of these growths were excised. There was no local recurrence, but six months later a lump was removed from the right axilla. Within six months from the removal of this nodule the skin of the arms and trunk was studded with melanotic nodules of various sizes and at different depths, and there was only the outlook of a speedy death.

Sterilization of Rubber Catheters.—A simple and practical method of sterilizing soft rubber catheters is given by WOOLF, in the *Centralbl. f. d. krank. Harn. u. Sexual-organe*, vol. viii, p. 285. After use, the infected catheter is washed with water and put into a 5-per-cent. formalin-glycerin solution. There it remains during one day and is then put into glycerin. These substances are kept either in long test-tubes, or in suitable lengths of inch glass tubing with corked ends, each catheter having its own tube. The transfer from one tube to the other is made without touching the vesical end of the instrument. For use, the catheter is taken out and dipped without washing into a glass containing a 20-per-cent. solution of sugar in glycerin. This lubricates it well. All of these solutions are easy to sterilize by boiling, and the catheters may be boiled in their tubes, with or without a water bath, without injury.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

APPARENT DEATH AND PREMATURE BURIAL.

DURING the passed year this subject has been widely discussed on the continent of Europe and in the English press, and has engaged public attention to an unusual degree. This has resulted in the formation of societies whose avowed purpose is the prevention of premature burial. Cases of *live* sepulture are certainly rare in all civilized countries; nevertheless, no experience can be more horrible than that of being buried alive, and the occurrence of a single case in a generation is sufficient to stimulate the most scientific research into preventive methods. Ordinarily, a person is pronounced dead when signs of respiration have disappeared and the heart has ceased to beat. Cases, however, are upon record in which people have gone into a state of trance in which these tests have been set at naught, and the patient has again resumed the active functions of life. Since the state of trance and hypnotism has been more generally recognized by the profession, greater care has been observed in pronouncing upon suspicious cases, and in some countries in Europe the only absolute sign of death which is recognized is advanced or advancing decomposition. To apply

this test in all cases, it would be necessary to have skilfully managed waiting mortuaries in which bodies could lie until decomposition begins. Such mortuaries are to be found in certain parts of Austria and Germany, but to be of universal application, they would have to be very numerous, and this would involve greater expense than the necessity of the case seems to justify.

The late Sir Benjamin Richardson, who had made the condition of trance, catalepsy, and other death-counterfeits the study of investigation, formulated the following tests as necessary to unequivocally establish the reality of dissolution: (1) Respiratory failure, including absence of visible movements of the chest, absence of the respiratory murmur, absence of condensation of moisture in the breath. (2) Cardiac failure, including absence of arterial pulsation, of cardiac motion, and of cardiac sounds. (3) Absence of turgescence, or filling of the veins, on making pressure between them and the heart. (4) Reduction of the temperature of the body below the normal standard (98° F., in the axilla). (5) *Rigor mortis* and muscular collapse. (6) Coagulation of the blood. (7) Putrefactive decomposition. (8) Absence of red color in semitransparent parts under the influence of powerful rays of light. (9) Absence of muscular contraction under the stimulus of galvanism, of heat, and of puncture. (10) Absence of the red blush of the skin after subcutaneous injection of ammonia (Montiverdi's test). (11) Absence of the signs of rust or oxidation of a bright steel blade, after plunging it deeply into the tissues (the needle test of Cloquet and Laborde).

In a book written on the subject of premature burial, a review of which appears in *La Médecine Moderne*, February 24, 1897, the author, Icard, maintains that the only certain proof of death is the *absolute* cessation of circulation. He emphasizes absolute because the pulsations of the heart may be imperceptible although the circulation still continues. Icard believes that he has discovered in *absorption* an infallible method of determining whether or not circulation has ceased. If any substance be injected into a corpse it will remain at the point of injection. If circulation is present, no matter how feeble, a portion of the injected substance will be carried away, and its presence may be demonstrated in other portions of the body; if this takes place the individ-

ual is not yet dead, no matter what other signs of death may exist. The substance used for this purpose should be soluble in water, non-toxic, easily recognizable in minute quantities, and one which is not present in any portion of the human body either normally or accidentally. There are many substances which fulfill these requirements, such as the ferrocyanids of sodium and potassium, some of the iodids, etc., but the best of all is fluorescein. Dissolved in an alkali, this substance produces a beautiful fluorescent green, while its power of coloring is so strong that a sixth of a grain will distinctly color 100 gallons of water. By experiments upon dogs, cats, rabbits, and guinea-pigs, Icard found that 10 grains of fluorescein are more than sufficient to produce in an adult a characteristic reaction. In order, therefore, to determine the death of a person, 2 drams of the following solution are injected hypodermically:

R. Fluorescein	3 ij
Sodæ carbonat. . . .	3 ij
Aquæ distil., q.s. ad. . .	5 ij.

If circulation is present, there will become evident an emerald-green color of the cornea of the eye, of the skin, and of the urine. The coloration of the blood itself is determined by passing underneath the skin one or two cotton threads in order to soak up blood and serum. These are then placed in a test-tube and two teaspoonfuls of water are added, and the mixture is boiled to destroy the red coloring matter of the blood. If there is any fluorescein present, its green color will become apparent.

ECHOES AND NEWS.

A Horse with False Teeth.—A valuable horse belonging to a Louisville, Ky., man enjoys the distinction of being the only horse wearing false teeth.

Michigan Peppermint.—It is said that more than one-half of the peppermint, spearmint, tansy, and wormwood consumed in the entire world is raised and distilled in Michigan.

Chlorate of Potash as a Poison.—Another death from an overdose of chlorate of potash is reported from Vienna. The present case is that of a woman who took 25 grams of the drug.

Quarantine in New York.—The first quarantine in the harbor of New York was established in 1737, and was due to reports that smallpox and spotted fever were raging in South Carolina.

Diphtheria from Chewing Gum.—A family of children at Westchester, Pa., was infected with diphtheria by chewing gum which had been chewed by a child while suffering from the first symptoms of the disease.

Women Medical Students.—The College of Physicians and Surgeons of Chicago, Ill., will henceforth admit women students, by order of the trustees of the University of Illinois, of which it was recently made a department.

Where Life Is Long.—It is said that in Norway the average length of life is greater than in any other country on the globe. This is supposed to be due to the fact that the temperature is cool and uniform throughout the entire year.

Death of Dr. A. F. E. Krog.—Dr. Albert F. E. Krog was found dead in his office at 233 East Fourteenth street, New York, on the 10th inst. He had been an invalid for some time and was quite feeble. Death was due to heart disease.

Memorial to John and William Hunter.—At a public meeting recently held in Glasgow it was proposed to collect a fund for a memorial to John and William Hunter, the great physiologists. The subscription list was headed by a gift of \$4250.

A Special Hospital for Patients Suffering from Tinea.—The Lailler Hospital and School, for children suffering from tinea, has just been opened in Paris. It affords accommodation for 300 patients, and its maintenance will cost \$40,000 annually.

Facts about Bananas.—The *Medical Times* says that bananas should never be eaten raw, for they are full of germs, besides being indigestible. Three bananas, weighing one pound, when baked equal in nourishment twenty-six pounds of bread.

Death's Big Harvest.—Bombay officials are greatly alarmed over the death-rate of the past week. Of the 1071 deaths 220 were due to cholera and 18 to plague. The total death-rate is equal to 65.61 per thousand, or double the normal rate.

Death of Dr. Arthur S. Kennedy.—Dr. Arthur S. Kennedy of Auburn, N. Y., recently lost his life as a result of the accidental discharge of his gun while hunting. Dr. Kennedy was fifty-five years of age and had retired from active practice some time ago.

Memorial to Greig Smith.—The colleagues of Greig Smith have decided to make an appeal for subscriptions to provide a bust or medallion, to be placed in the Bristol Museum or in the operating-theater of the Bristol Royal Infirmary, to perpetuate his memory.

Inflated the Baby.—A little boy of Beaver Falls, Pa., placed the tube of a bicycle pump in a baby's mouth and began pumping in air. The child's stomach swelled like a balloon, and in a few minutes she became unconscious. The mother arrived in time to save the child's life.

A Gold Medal for Professor Behring.—A gold medal and a purse of 1000 marks have been presented by the University of Würzburg to Professor Behring for his discovery of the diphtheria antitoxin, which is considered the most important discovery made during the past three years.

Typhoid among the Striking Miners.—The news comes from Pittsburg that typhoid fever in a mild form is raging in the vicinity of Camp Determination at Turtle Creek. Sixty cases, with five deaths, have occurred so far. Bad water and a lack of sewerage are the cause of the epidemic.

Poorhouse Scandal.—Charges of ill-treatment and neglect have been made against the keeper of the poorhouse at Passaic, N. J. Upon investigation the place was found to be in a filthy condition, alive with vermin, and the inmates ill-fed and neglected. The keeper will probably be discharged.

Needle in a Baby's Back.—A Morristown, N. J., baby was being undressed recently, when the nurse scratched her hand on a sharp point protruding from the child's back. Upon investigation this was discovered to be the point of a needle, which, upon being withdrawn, was found to be unbroken.

Skulls in the Street.—A heavy rain storm swept away part of the embankment of an old cemetery at Paterson, N. J., last week, and, as a result, several skulls and other human bones were washed out of graves and swept into the street. They were turned over to the coroner, who had them reburied.

Black Clothing Unhealthy.—A physician in Philadelphia recently told a woman who consulted him that he would not prescribe for her if she persisted in wearing black or somber clothing, as he considered her "peculiarly nervous and neurotic condition" partially due to the depressing effect of her garments.

A Prize for the Discovery of the Bacillus of Yellow Fever.—One-half of the prize of \$220,000 which the government of Brazil is to present to the author of a work demonstrating the existence of the bacillus of yellow fever and to the discoverer of an effective treatment of the disease, will probably be awarded to Sanarelli.

Bogus University Degrees.—It seems that the National University of Chicago is pursuing its nefarious business across the water. The British Government is considering the advisability of prosecuting, on the charge of obtaining money by false pretenses, the agents of this institution for offering to confer degrees for \$5 each.

To Rid Cattle of Texas Ticks.—In order to rid them of ticks, and in this way destroy the germs of Texas fever, 200 cattle were dipped recently in chloronaphtholeum at Fort Worth, Tex., under the direction of Dr. Nergard, of the Department of Animal Industry. A quarantine against infected cattle has been declared in St. Louis.

Fourth Congress for the Study of Tuberculosis.—The fourth congress for the study of tuberculosis will be held in Paris

during the last week of July, 1898. The following questions will be discussed: "Sanitaria for Consumptives;" "Serums and Toxins;" "The X-ray in Diagnosis and Treatment," and "Tuberculosis in the Lower Animals."

No More Smallpox.—Dr. Benedict, of the Bureau of Contagious Diseases, reports that there have been no cases of smallpox reported in the city of New York since July 14th, and that the small epidemic of the disease which caused a little uneasiness has been entirely crushed out. In all, seventy-two cases were reported between March 14th and July 14th.

Vaccine for Drunkenness.—The news comes from San Francisco that Dr. F. W. D. Evelyn of St. Luke's Hospital of that city has made public the results of fifteen-years' experiments by which he claims to have found a certain cure for drunkenness. The remedy consists of the inoculation of a substance obtained from the blood of a horse into which alcohol has been injected.

Science and Ice Cream.—The British Institute has been investigating ice cream and has discovered that the kind which is sold on the street, popularly known as "hokey-pokey," contains various insects, legs, wings, straw, hair, coal-dust, woolen and linen fiber, tobacco, muscular tissue, and 7,000,000 microbes per cubic centimeter. The better grades of ice cream were found to contain numerous microorganisms and ptomaines.

For People Buried Alive.—An apparatus has been constructed by a Russian inventor by which anybody who is unfortunate enough to be buried alive can give warning of the fact. The device consists of a button situated on the inside of the coffin immediately over the breast of the individual placed in it. If he should come to life and begin to breathe, the expansion of the chest will press the button and set going an alarm bell in the office of the superintendent of the cemetery.

Mosquitoes as Carriers of Infection.—The remarkable number of serious cases of poisoning from mosquito-bites which have been reported during the present summer, adds additional confirmation to the theory that mosquitoes may act as carriers of infection. The unusual humidity of the atmosphere, due to the continuous rains combined with the high temperature, have favored the development of mosquitoes and they have been unusually abundant and vicious in every part of the country.

Queens County Almshouse Scandal.—Official investigation of the management of the Queens County almshouses has brought to light a shocking state of affairs at the Barnum's Island almshouse. One of the women inmates has given birth to four children during her stay there, and another woman was found who had recently given birth to one. Utter disregard of even ordinary methods of disassociating the sexes is shown in all the institutions, and at Barnum's Island the male and female wards are not even separated by adequate partitions.

The Rocky Mountain Interstate Medical Association.—The organization of this new Association, composed of mem-

bers of the regular profession residing in Colorado, Utah, Montana, Idaho, Wyoming, New Mexico, and Arizona, was perfected at Salt Lake City, Utah, on July 24th, by representatives from four of the States named. Dr. C. P. Hough of Salt Lake City, was elected president; Dr. C. K. Cole of Helena, Mont., first vice-president; Dr. Clayton Parkhill of Denver, Col., second vice-president, and Dr. E. Stemer of Rawlins, Wyo., secretary and treasurer. The first meeting will be held at Denver in June, 1898, during the meeting of the American Medical Association.

Experiments with a Human Body.—In order to ascertain whether it is possible for a human body to be completely dissolved by submerging it in a solution of crude potash, the experiment was tried recently at the Rush Medical College, Chicago, and the results may enable the State of Illinois to convict one Leutgert, a sausage manufacturer, who is accused of killing his wife and making away with the body by subjecting it to the action of potash. The experiment showed that after a cadaver had remained in the bath for a specified length of time, nothing remained of it but a few bits of bone, which, presumably, also would have become dissolved if allowed to lie longer in the solution.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

RESULTS OF THE STATE BOARD EXAMINATIONS—THE AMERICAN PUBLIC HEALTH ASSOCIATION'S MEETING—A LOW DEATH-RATE FOR PHILADELPHIA FOR THE FIRST SIX MONTHS OF 1897—A NEW GROUP OF BUILDINGS FOR THE PENNSYLVANIA INSTITUTION FOR THE BLIND—VITAL STATISTICS FOR THE WEEK ENDING AUGUST 14TH.

PHILADELPHIA, August 14, 1897.

OF the 445 candidates for licenses to practise medicine in Pennsylvania, who were examined by the State Board of Medical Examiners in June, 1897, eighty-three failed to pass successfully. Of the total number of candidates twenty were women, of whom seven failed.

This high percentage of failures, which is over five per cent. in excess of that met with in previous examinations, cannot be explained by the plea of the severity of the examination, for it is generally understood that the questions asked of this year's candidates were eminently fair and practical. The results, therefore, must be taken to demonstrate that there is a need for a more thorough preliminary training for students of medicine, and this is a need which medical colleges who care anything for the reputation of their graduates before the public cannot afford to disregard. It is gratifying to remember, however, that such steps have been, or are being, taken by the medical schools of this State generally, although these measures, if we gauge their efficiency by the reports of the State Board Examiners, have apparently been too recently carried out to visibly affect the showing of their graduates. Another year, or another two years, at the

most should remedy this very apparent flaw in the requirements for the doctorate in medicine.

The local committee of the American Public Health Association, which is to hold its twenty-fifth annual meeting in this city next October, has completed the arrangements for the forthcoming meeting by announcing the various committees on arrangements, finance, exhibits, and other departments, and by mapping out the work of the Association as far as it is possible for a local committee to do. The secretary, Dr. Benjamin Lee, gives prominence to the fact that the local and State membership of the Association is not at all what it should be, and he is making determined efforts to secure the accession of a large number of new members from Pennsylvania and neighboring States before the time set for the Association's coming meeting. From present indications, the scientific work of the meeting promises to uphold the high standard of excellence which has attended the transactions of this body during the twenty-five years of its existence, and it is proposed to give no small thought to the social aspect of the convention—a matter in which Philadelphia takes a certain amount of pardonable pride.

With a population of 1,215,000, the death-rate in Philadelphia for the first six months of 1897 has been only 18.14 per 1000 of population, while for the past ten years the average mortality has ranged from 20.64 to as high as 22.86 per 1000. The decrease has, however, been almost entirely confined to adults, for while a comparatively cool summer caused a decided falling off in the usual number of deaths from cholera infantum and other diseases which usually cause such a high death-rate in infants, there has been a notable increase in deaths from diphtheria and scarlet fever, with the result that the mortality in children has not been lowered.

It is a notable fact that among adults, for the first time in the history of the city, pneumonia has taken first place as a cause of death, supplanting pulmonary tuberculosis, which has heretofore ranked far ahead of other diseases in the number of its victims. This is held to be due, at least partly, to the stringent measures against tuberculosis which have been taken for some months past by the Board of Health, both in the general distribution of printed matter on the subject, and in the rigid inspection of food articles exposed to the influences of this disease.

Plans have been completed for the new buildings of the Pennsylvania Institution for the Blind, which are to cost in the neighborhood of \$300,000. The main building is to be built on the old Spanish monastery plan, surrounding two handsome cloisters; it will measure 361 x 222 feet, and will contain the class-rooms, and pupils' dormitories, together with a large auditorium and gymnasium. The construction of several detached buildings is also contemplated, to be used for various purposes. The main building will be modeled on historic lines, with broad stone corridors, and will contain the latest facilities for the instruction of the blind, many of which originated in this well-known institution.

The number of deaths occurring in Philadelphia for the week ending August 14th, was 406, a decrease of 6 from the preceding week. Of the total deaths, 173 occurred

in children under five years of age. There were 21 deaths from diphtheria, 4 from scarlet fever, and 9 from typhoid fever. The total number of new cases of contagious diseases for the week was 202.

LETTER FROM ATHENS.

[Special Correspondence of THE MEDICAL NEWS.]

THE MEDICAL DEPARTMENT OF THE GREEK ARMY—ABSENCE OF ORGANIZATION OF FIRST AID TO THE INJURED—THE WORK OF THE RED CROSS SOCIETIES—ABUSE OF THE GENEVA INSIGNIA—RATIONS AND CAMP SANITATION—DIFFICULTIES IN THE WAY OF OBTAINING TRUSTWORTHY INFORMATION AS TO MORTALITY FOLLOWING INJURY AND OPERATIONS.

ATHENS, GREECE, July 28, 1897.

ARMED with a card of introduction from the American minister, and accompanied by Dr. Achilles Rose of New York, who is spending the summer in Athens, and who acted as interpreter, a visit was made to the War Office, where we were most courteously received. Upon making known our desire to learn something of the organization and work of the Medical Department of the Greek army during the late war, we were referred to the surgeon-general's office. We found that functionary installed in a 12 x 14 apartment, and, from the absence of evidences of system, we were in a measure prepared for what followed our inquiries. A most courteous and obliging young medical officer was assigned to our service, and our investigations commenced at once.

Very little information as to the organization of the Medical Corps or the methods of relief to the injured upon the field could be obtained. It was very evident that the outbreak of hostilities found the Medical Department of the Greek army as little prepared for the work at hand as the other departments. We had previously learned from some Red Cross nurses sent out from England, and who had just returned from the scenes of the recent conflicts in Thessaly, that there was practically no first aid near the actively engaged lines. As a result of this, many died from hemorrhage who, without doubt, could have been saved by simple provisional methods. The presence of the first aid organizations was practically forbidden. This was not denied at the surgeon-general's office, and was confirmed by statements obtained from patients in the hospitals whom we afterward saw. According to the latter, five days elapsed, in some instances, between the reception of the injury and the first dressing.

It is probably true that the medical department was not only greatly hampered by absence of efficient organization, but by lack of proper facilities for carrying on the work as well. We were not able to obtain an inspection of a field outfit of instruments, and the failure of our efforts in this direction aroused the suspicion that there was very little in this line to show us. At one of the hospitals we were shown what would have been a fair outfit for a small civil hospital, with the statement that it had been the gift of a wealthy foreign lady who sympathized with the Greeks in their struggles against the Turks.

The English Red Cross Society furnished six surgeons.

In addition to this a corps of trained nurses was sent out by the London *Daily Chronicle*. These did most efficient work. Besides this the German and French organizations furnished each a complete hospital outfit of 120 beds, with surgeons, assistants, and nurses.

The charge has been made that the Turks refused to respect the Geneva Cross. I am informed that this arose from the fact that the Greek irregulars employed the insignia to cover an attack upon the Turkish troops, and that, naturally enough, the latter were thereafter suspicious of the display of this emblem.

The rations of the Greek soldiers consisted mainly of bread and cheese. Camp sanitation is said to be almost unknown. Laxity in respect to the latter is not to be wondered at when it is considered that even the ordinary discipline of camp life is disregarded. Roll-call is more honored in the breach than in the observance, and drills, inspection, and review are almost unknown.

It is impossible to ascertain the mortality among those injured in battle. This arises partly from the absence of records available for the purposes of study, and partly from a disinclination on the part of the combatants to acknowledge serious losses. Judging from the impressions received, the opportunities for studying results of gunshot wounds and their treatment afforded by this conflict will be comparatively slight. As far as the available sources of information could furnish knowledge upon the subject, it was ascertained that 3000 wounded were cared for in Athens. These were transported to the city from the districts where the fighting took place, partly by boat and partly by wheeled ambulances. No railroads were available for the purpose. Of these, about one-half were cared for in the Ecolé Hypaxiomaton and the Ecolé Evelpidon, two government military schools of Athens which were converted into temporary hospitals for the purpose. The remainder were cared for in the Military Hospital and the Evangelical Hospital under Professor Galvani.

Nearly all operations were performed before the patients were brought to Athens, and, therefore, it is impossible to ascertain anything concerning the immediate mortality following these, or that occurring among those not operated upon. Those who survived the shock and hemorrhage, in both instances, as well as the transportation over mountain roads, were naturally the most vigorous subjects, and the most likely to recover.

A round of the hospitals occupied portions of two days: Most of the injured were suffering from gunshot wounds, and these from wounds inflicted by the comparatively heavy Peabody-Martini rifle ball. This arm seems to have been generally used by the Turkish troops. Here and there a smaller wound of entrance suggested a Mauser bullet, but these were few and not easy of identification. The Greek surgeons spoke with pride of two cases of gunshot wounds of the abdomen, one of which involved the liver, and which recovered without laparotomy. A shrug of the shoulders and a roll of the eyes were the only answers to the query as to how many had died following such injuries.

From the stories current of the fierceness of the Turkish cavalry charges it was expected that wounds from cut-

las strokes and saber thrusts would be presented. But one such was shown us. A Greek officer informed us that in no instance did a hand-to-hand conflict take place; hence the absence of this class of injuries. Only two cases of shell and shrapnel injuries were found.

Most of those shown were well on the road to recovery. In most instances there were evidences present of suppurative action, although some surprisingly good results following penetrating wounds of joints were exhibited. The first dressing consisted of iodoform gauze, cotton, and gauze bandages wrung out in sublimate solution. Whenever the emergency would permit the surrounding parts were cleansed and shaved as a part of the treatment. In cases complicated by fracture the parts were supported by means of ready-made splints of French manufacture.

Most of the Greek military surgeons have received their education in part in Germany. The shortcomings of the medical department are due, not so much to lack of intelligence as to absence of system and organization, without which, in the face of the dire emergencies of war, the efforts of the highest order of talent or the brightest flashes of genius are doomed to disappointment and defeat.

GEORGE RYERSON FOWLER, M.D.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE NERVOUS LESIONS OF INFANTILE CONVULSIONS—PROFESSOR PALTAUF'S DEMONSTRATION THAT ONLY A SPECIFIC STREPTOCOCCIC SERUM IS OF THERAPEUTIC VALUE—THE DREAD OF LEPROSY CONTAGION.

VIENNA, August 1, 1897.

A RECENT report from Professor Obersteiner's Laboratory of Nervous Pathology here in Vienna seems to show that there are certain definite nervous changes concerned in the immediate etiology of infantile convulsions. The specimens examined came from two nurslings who had had characteristic convulsions. The examination of the spinal cords, after staining by Marchi's method, clearly showed degenerative processes in the anterior nerve-roots, the degeneration reaching to the anterior horns, and being especially noticeable in the cervical and lumbar enlargements. The upper cervical roots were but very slightly affected, and those of the dorsal region not at all. While the hardening in Müller's fluid, necessary for the carrying out of Marchi's method of examination, made it impossible to apply that of Nissl, the most reliable test for the presence of cellular degeneration, according to the older rules of staining, there seemed to be degenerative processes at work in the anterior horn cells as well, though in the initiative stage. Dr. Zappert, who reports the findings, has examined the cords of more than one-hundred infants, and considers that the presence of such changes is very frequent. The motor-nerve apparatus in a rapidly growing child seems to be intensely sensitive to toxic influences. Seemingly slight infections produce sufficient toxins to affect tissues which react so easily.

Here, as in other departments of medicine, the rôle of idiopathic disease is decreasing in importance, that of in-

fection taking its place. In almost the same way, also, reflex troubles supposed to be due to intense irritation of sensitive nerve endings, reacting on corresponding or sometimes even distant motor nerves, are being brought more and more under the head of infectious processes. Teething and summer diarrhea are the mediate and not the immediate causes of convulsions, the weakened state of the system, with consequent infection and absorption of toxins, instead of the intense irritation of peripheral nerves being the cause of the nervous explosion along motor-nerve tracts.

It is thought that like changes in spinal nerve cells and roots will be found as the explanation of such affections as diphtheritic paralysis and pseudoparalysis syphilitica, the general process in these conditions being a similar, though much more intense one than that observed in the production of ordinary infantile convulsions. That anterior poliomyelitis is a consequence of infection from intestinal toxins, our American statistics, showing its increased frequency during the summer months, have long since made clear. This demonstration that probably every case of infantile convulsions is associated with more or less pathologic change in the anterior horns and roots, is extremely interesting, and may help to explain the occurrence of central nerve degenerations and muscular atrophies in later life quite as well as scarlet fever explains the occurrence of Bright's disease, or rheumatism that of valvular lesions of the heart.

Professor Paltauf, whose thoroughly conservative though eminently scientific appreciation of advances in bacteriology and serotherapy is well known, has been giving some very interesting demonstrations of the specific therapeutic properties of various streptococcic serums. Animals have been inoculated in each ear with definite amounts of cultures of different forms of streptococci, and have then been injected with a streptococcic serum prepared by the gradual immunization of animals with ascending doses of one of the varieties of streptococcus. This never fails to put an end to the pathologic process produced by the affiliated streptococci, but has very little or no effect on the local inflammatory and general constitutional symptoms caused by the other form. To have any effect on the latter, the serum must be used in very large doses, and even then its action is not sure and radically curative.

Meantime, however, there are any number of reports of the success or failure of streptococcic serum, especially in puerperal cases. Often enough cases of puerperal sepsis are due to the presence of other bacteria than streptococci, but even when the latter are demonstrable it would seem to be all important to determine the specific variety which is at work. As was the case with diphtheria serum when injected for what was really a streptococcic infection in certain cases, the reputation of Marmorek's serum is liable to suffer when employed promiscuously, and for cases with which it has not the slightest biologic connection. Unfortunately, the varieties of streptococci are not so well differentiated by bacteriologists themselves as to make the use of a specific streptococcic serum easy for the practitioner. Meantime it will be employed in many cases, but always with other avail-

able therapeutic measures, and discouraging reports must not be given too much weight, as the solid foundation of its antitoxic specificity has been too clearly demonstrated experimentally for it not to prove ultimately of value.

The leprosy scare, which occurs periodically in different parts of the world, took place in the Dalmatian province of the Austrian Empire not long ago. A series of cases of a severe chronic skin disease occurred in a certain family, and finally the neighbors began to shun its members. Then it was noised about that they were lepers. The rumor came to the ears of the Austrian officials that leprosy was endemic in the province, and a medical man was sent to investigate. He reported that the rumor was utterly unfounded, but public opinion was not satisfied until Professor Neumann, who has devoted a good deal of study to leprosy in Norway, Sweden, and Iceland, went down to Dalmatia, brought one of the patients back with him, and demonstrated the case as one which Dühring, Thost and Unna have described as *ichthyosis palmaris et plantaris cornea*, or *keratoma palmare et plantare hereditarium*, an extremely chronic affection often producing very unsightly deformities of the hands and feet, the heredity of which may be traced through three or four generations. For it, Professor Neumann suggests the name "*keratosis hereditaria*."

I notice by the American medical journals and by the daily papers that a leprosy case has disturbed the sisterly relations of two of our important cities. This seems amusing here where the general teaching is that leprosy is almost absolutely, if not quite, non-contagious. Patients affected with it are treated in the ordinary wards for skin diseases, and pass around for general examinations during clinics. It is to be hoped that the publicity given to the present medical teaching on the subject as the result of the Leprosy Congress in Berlin in the fall will do something toward modifying the tendency of public opinion to make life more unbearable than it is for such unfortunate patients.

TRANSACTIONS OF FOREIGN SOCIETIES.

THE CONGRESS FOR INTERNAL MEDICINE, BERLIN.

THE Fifteenth Annual Congress of Internal Medicine was held at Berlin, June 9 to 12, 1897. This association, which has a membership of about 350, has upon its roll the names of the most celebrated physicians of Germany and Austria. It was at the first congress, held during April, 1882, that Koch announced his discovery of the bacillus of tuberculosis. Since that time many other important papers have been read at its sessions. The report of this year's proceedings which is given in these columns will be found to contain in a condensed form the most valuable of the communications presented.

BAUMLER, who read a paper on *chronic rheumatic arthritis*, spoke of the misuse of the term *rheumatism*, which is made to include cases of neuritis, tabes, periostitis, and gonorrheal arthritis. Properly speaking, "chronic rheumatism" is a chronic form of the acute. These are the cases in which repeated attacks of the acute affection which have not been treated for sufficient time, or

not with sufficient care, develop into a chronic form of the acute disease. Since the introduction of the salicylic treatment of acute rheumatism, these cases of chronic rheumatism have become much more rare. Excluding these from consideration, as well as the cases in which the joint affections are tuberculous, gonorrheal, or syphilitic, or due to some infectious disease, there remain the cases of polyarticular inflammation, with destruction of the joint surfaces, deposit of lime salts producing deformity, and often partial or complete disability. Hence the name "*arthritis deformans*."

The distressing course of this disease when untreated, leaving the patient at last bedridden, is familiar enough to every physician. Whether it is curable in its early stages is still a matter of dispute. Certainly no effort should be spared to accomplish this result if possible.

Trauma, in the widest significance of that term, is an important etiologic factor, as are dampness and cold in sleeping apartments, or in workrooms, though this has been denied by some authors. At any rate, the term "poor-man's gout" is inaccurate, as the disease is as common among the rich as the poor. Women are much oftener affected than men. This has been explained by attributing to the disease a reflex origin, the source of irritation being in the genitals. According to others the cause is an infectious agent, and the outbreak of the trouble in several joints lends credence to this view. Several investigators have announced the discovery of a specific bacillus, but thus far no one has succeeded in producing the disease by inoculation.

OTT said that the object of treatment is to get the patient as quickly as possible over each acute attack. As long as fever continues, absolute rest is to be observed and hot wet compresses applied to the affected joints. If the pain is very great, chloroform liniment or salves containing opium, or morphin injections, are to be employed. The benefit which formerly was sought by the use of the actual cautery may be more simply obtained by repeated applications of tincture of iodine. As internal remedies, aconite, colchicum, and guaiacol formerly were thought much of, and after them, salicylic acid; but valuable as this remedy is in the acute affection, its power is limited in the chronic, and antipyrin, acetanilid, phenacetin, phenocoll, and malakin are far better. If the swelling of a joint with serum is very great, puncture of the joint capsule, and escape of the serous fluid, will give relief.

When the acute symptoms have subsided, circulation around the joint should be stimulated, in order to further absorption of the exudate. Iodine and ichthyol are serviceable at this stage, and baths of the greatest variety, of water, fresh and salt, air, mud, sand, steam, etc., have all been praised, and justly. The essential principle in all of them is the heat. A valuable application of this is seen in the introduction of the affected joint into a chamber where the air is heated to 104° to 119° C. (220° to 246° F.). The limb sweats profusely, and the joint even after one treatment is much softer and more movable. Douches of hot water, or alternate hot and cold streams, massage, and passive and active motions, and electricity,

all are of use while acute symptoms are absent, and all must be suspended if acute symptoms return.

CHVOSTEK has found the blood and extravasations of rheumatic joints almost always sterile; and the idea of a specific micro-organism producing acute rheumatism must be given up. The characteristics of the disease are not sufficiently fixed; they are simply a swelling of the joints, and a short duration, and both symptoms are better explained by the action of toxins than by that of living bacteria.

A paper on *epilepsy* by UNVERRICHT was largely devoted to the nature of the disease. The reader inclined to the cortical, as opposed to the medullary theory. Epilepsy is only a name for a set of symptoms which will lose the significance of a genuine disease as soon as the true causes of the seizures, in different cases, are better understood. In alcoholic, lead, syphilitic, and uremic convulsions the epilepsy is recognized to be only a symptom; and as our knowledge extends, the applicability of the term "true epilepsy" will become less and less.

VIERORDT spoke of the use of iodine in diseases of the vessels, and especially in angina pectoris. During five years he has employed this drug in all cases of arteriosclerosis, with the exception of patients with bad heart lesions or marked albuminuria, with satisfactory results. From 15 to 45 grains of iodide of soda are given daily in divided doses in vichy or milk, for several months, or, with intervals of rest, for a much longer time. If necessary, digitalis or nitroglycerin may be given at the same time. The good results have been beyond question. Many of the patients had already obtained all the benefit possible from a careful dietetic and constitutional treatment before being placed in his care; but by a long-continued course of the iodids, they were relieved of severe angina, were able once more to go about, something which had for a long time been impossible without great pain, and in short were again able to resume their customary occupations.

The action of the iodide is not clearly understood. It probably brings to a standstill the sclerotic process in the vessels, which otherwise would be continually progressing. As a result of this, the increased blood pressure gradually sinks, and when this is accomplished, it suffices for the restoration of function for a long time. There is no proof that the iodide has any action tending to restore the vessels already affected.

EULENBURG discussed the *Three Theories of Exophthalmic Goiter*—hematogenous, neurogenous, and thyrogenous. The hematogenous theory, which was advanced by Basedow, rests on the fact that the disease is so much more frequent in women than men, and is so closely associated with disturbances of menstruation, beginning pregnancy, etc.

Advocates of the neurogenous theory sometimes look for the cause of the disease in the sympathetic nerves, sometimes in the vagus, and sometimes in the central nervous system. This theory finds support in the hereditary tendency of goiter, in its occurrence after traumatism, shock, etc., and in its association with epilepsy, hemi-

crania, and chorea, as well as with paralyses, astasia, abasia, diabetes and many other diseases.

The thyrogenous theory presupposes not merely an increased amount of secretion by the thyroid gland, but an altered secretion as well; and that the changed products of the gland circulating in the blood exert a toxic influence upon certain of the tissues, presumably those of the nervous system. In accordance with this theory, surgical treatment of exophthalmic goiter has come into being, and strumectomy, with possibly an after treatment with thyroid extract, is a well-recognized procedure. Truly, in most cases it is a method of treatment which can well be spared, as, unless there are marked local symptoms, treatment by medicine gives equally satisfactory or even better results.

BENEDIKT summed up the *Applicability of the Röntgen Rays to Internal Medicine*. By their use we have first learned the exact range of the heart's activity—something which has been greatly overestimated—its comparative freedom from the diaphragm and its suspension from the great vessels. Moreover, the size of the heart and the exact location of its apex can now definitely be determined, even though covered by the lung, and in case of hypertrophy the exact part involved can be plainly seen. We may see the organ take the form of sucking, and can watch its rotation; if there is dilatation it may be followed from day to day, in order to observe the effect upon it of the remedies employed.

The action of the respiratory muscles, in health and in abnormal conditions, and the presence in the lungs or pleuræ of consolidations are revealed by the variations in the translucence of the chest, by alterations in the position and action of the heart, etc. The diagnosis of new growths is made easier and more certain. The rays are a help in the early diagnosis of tuberculosis of the vertebræ. In abdominal troubles they have not proved so serviceable; though certain stones, notably phosphates and oxalates, have been located by their use. For the exact localization of foreign bodies, in the esophagus and elsewhere, the rays are naturally of great assistance.

LEVY-DORN called attention to the fact that by the help of the rays the diagnosis of aneurism of the aorta can be made at a time when no other method of diagnosis will reveal its presence. The chance that treatment will result in a cure, is therefore increased.

BEECHER has found that the bones in an extremity show with much greater clearness, if the limb first be rendered bloodless with an Esmarch bandage before exposure to the rays.

In a paper, entitled the *Limits of Modern Drugs*, LIEBRICH made an attack upon the advocates of serum treatment. The bacteria, he said, are often not the real cause of disease, but they direct themselves against the body, the power of resistance of which is already lowered. How often one sees tuberculosis of a single organ, without resulting phthisis, just as tubercle bacilli exist in the bronchi of healthy men, and do not cause the disease. Before the bacillus can enter the lung, this must first be diseased; and therefore it is hopeless to try to heal phthisis by destroying the bacilli. If this were done, the disease would

remain and the lung would simply become the harbor for other parasites. We must look to "cellular excitants" for a real cure, and these exist, not merely in fresh air and diet, but also in the pharmacopœia. A most valuable remedy of this class is cantharidin.

The discussion of this paper led to a presentation of the already familiar arguments for and against the use of antitoxin in diphtheria. Speakers on each side admitted that the decision of this much-disputed point must finally rest with practising physicians, and not with scientific experimenters.

RUMPF has investigated the *Disposition of the Lime Salts in Heart Disease*, and finds, (1) that if lime salts are given freely, a considerable portion remains in the body; (2) that in patients with calcification of the vessels, there also may be a diminution of the excretion of lime salts as compared with their introduction; (3) that the amount of lime in the blood varies both in health and disease. The writer, therefore, concludes that in certain diseases it may be advantageous to reduce the ingestion of lime salts. From further experiments with different kinds of food, he has been led to believe that a mixed diet is better for cardiac cases than a diet limited to flesh and fat.

On the Significance of Stimulation for Pathology and Therapy in the Light of the Theory of the Neuron, was the title of a paper by GOLDSCHNEIDER. The theory of the neuron rests upon the supposition that the nervous system is not a continuous path for transmitted influences, like a system of telegraph wires, but that every cell with its axis cylinder and its dendritic processes is an independent entity of a functional and nutritive nature. The neurons are not united—they only touch mechanically. If excitement rises high enough in one neuron, it is communicated to the next. Every neuron has its particular swell of excitability, that is, a certain pitch of excitement which it must reach in order to become active. This property of a neuron is for it an inherited and lasting one. All the neurons of the central nervous system are in touch; therefore, a sufficiently powerful irritation may spread over the whole tract. The stimulus travels along the line of least resistance, wherever the excitability has the swell of lowest value.

The excitability of the neurons can be so changed by irritation that the slightest stimulus will increase it, while strong ones will reduce it. This theory clears up many riddles in nervous diseases. It brings us also to new therapeutic resources. Thus, we may reduce an overexcitability of one part of the nervous system by rendering more sensitive another portion. In unilateral loss of sensibility it is evident that electricity to the unaffected side may restore the balance between the two sides, and this is borne out by the results of treatment. Hydrotherapy and massage produce good by calming the too excited neurons. Suggestion must be looked upon as a change in the degree of excitability of the neurons, either an increase or a decrease according to circumstances.

BEIN has been unable to produce mumps from cultures of a streptococcus found in that disease, in the duct of Steno, in parotid abscesses, and occasionally in the blood.

This streptococcus in appearance resembles the gonococcus and meningococcus, and is considered by Michaelis and others to be the specific germ of mumps.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICI- ANS AND GYNECOLOGISTS.

*Tenth Annual Meeting, Held at Niagara Falls, N. Y.,
August 17, 18, 19 and 20, 1897.*

FIRST DAY—AUGUST 17TH.

THE meeting was called to order at 9.30 A. M. by the President, DR. JAMES F. W. ROSS of Toronto. After certain preliminary business had been despatched and new members elected to membership, Dr. W. R. Campbell of Niagara Falls was introduced. He extended a welcome on the part of the Niagara Falls Academy of Medicine to the visitors. A cordial invitation was given to all to join in the entertainments which had been organized by that body during the session of the Association.

The first paper presented was by DR. WILLIAM WARREN POTTER of Buffalo on the subject of

PUERPERAL ECLAMPSIA, WITH SPECIAL REFERENCE TO TREATMENT.

The speaker said that at the Geneva Congress last year, M. Charpentier, a distinguished honorary Fellow of the Association and a recognized authority of high standing, gave expression to certain views regarding the treatment of puerperal eclampsia, especially as to the applicability of the induction of premature labor for its relief, which were so at variance to those which the speaker had been accustomed to harbor, and the soundness of which he had so frequently tested that he held no doubts concerning them. He had been greatly surprised that the views then brought forward had remained unchallenged. He thought that in the interest of professional progress and science these opinions of Charpentier should be opposed. His own observation and experience extended over a period of many years, and in the application of the principles advocated a measure of success had been obtained which did not present itself under a contrary method previously pursued.

The speaker said that it is a matter of great regret that we are still in doubt as to the pathogenesis of puerperal eclampsia. We are even forced to deny that it is a pathologic entity, and to affirm that it is but a group of symptoms which has been named "eclampsia" for the sake of convenience, or for the want of a better term. We are prepared to assert, as a result of progress already made, that it is not of hysteric, epileptic, or apoplectic origin; *i.e.*, that it is not produced in the human economy except in the pregnant or puerperal state. We might go further, and if possible agree that the convulsions are reflexes excited by cerebrospinal or medullary irritation of toxemic origin—a toxemia peculiar to pregnancy that has no parallel except during gestation.

After discussing in detail the probable causes of puerperal eclampsia, the speaker summed up as follows:

1. Though the pathogenesis is unsettled, it belongs solely to the pregnant, or puerperal state. It is not apoplectic, epileptic, or hysteric in character.

2. It depends upon toxemia due to over-production of toxins and under-elimination by the emunctories.

3. These toxins probably have their origin in the ingesta, in intestinal putrefaction, in fetal metabolism—one or all, and there is coexisting sluggishness and impairment or suspension of elimination.

4. When the prodromes of eclampsia appear the kidney should be interrogated as to its functions, and all symptoms carefully watched.

5. Treatment is (a) preventive, and (b) curative. Preventive treatment is medicinal and hygienic; curative treatment is medicinal and obstetric.

6. Milk diet and distilled water should be given during the pre-eclamptic state in order to dilute the poison, hasten its elimination and nourish the patient.

7. Blood-letting should be employed only in cases of plethora or cyanosis. It is liable to cause anemia if persisted in or repeated, whereas red blood-corpuscles must be conserved, not wasted. Glonoin diminishes vasomotor spasm, hence may be given freely in appropriate cases. Veratrum viride is a cardiac depressant and a dangerous remedy if pushed to an extent that will control the convulsions.

8. Eclampsia is the expression of a further maternal intolerance of the fetus; hence, as a primal measure, the uterus should be speedily emptied of its contents.

9. Medicinal treatment alone is a delusion, and when relied upon exclusively is fraught with danger, both to mother and fetus, whereas, in the prompt induction of labor is found a rational application of science to a desperate condition.

10. Finally, the induction of premature labor presents, in the present state of our knowledge, the only basis of expectation for a diminished mortality in a toxemic disease possessing a high death-rate.

In the discussion following the reading of this paper, DR. JOHN M. DUFF of Pittsburg said, in regard to the bringing about of premature labor in cases of eclampsia in which albuminuria is present, conscientious practitioners will not hesitate, although in exceptional cases careful attention to medicinal treatment will cause the albumin to disappear, and the patient will go on to normal labor. As a diuretic, he had obtained the best results from the use of milk as hot as could be taken by the patient with a spoon.

DR. H. W. LONGYEAR of Detroit said that the subject is one of extreme importance, and that he had been surprised that the essayist had not mentioned the necessity of inducing premature labor before the occurrence of eclamptic symptoms. Such treatment appeared analogous to snuffing out the light of a fuse after an explosion had occurred. Premature labor should be brought about, in his opinion, in every instance in which a daily examination of the urine shows a constantly increasing amount of albumin, with prodromal symptoms of toxemia. He had induced premature labor twice during the past year

under these circumstances, the patient in one instance being seven and one-half months' pregnant, and in the other, eight months'. He does not advocate this course merely because albumin is present in the urine, but because of this and the fact that the amount of urea eliminated is constantly decreasing. He considers the treatment by means of hot milk very valuable.

DR. WALTER B. CHASE of Brooklyn said that decrease in the daily amount of urea is a most valuable indication of the probable occurrence of toxemia in these cases. Unfortunately, many eclamptic patients are seen for the first time only when in convulsions, and then the production of premature labor is the single measure that can be relied upon. There are certain cases, however, in which the urine clears after a few days, and in these it is unjustifiable to end the period of gestation prematurely. For his own part, he considers that the best method of stopping the convulsions, especially when arterial pressure is high, is by the administration of veratrum viride. He believes its use to be unaccompanied by danger.

DR. W. H. WENNING of Cincinnati questioned the advisability of producing premature labor under all circumstances in which toxemic symptoms developed. In many instances if the os is rigid and not dilated there is danger of bringing on convulsions if the obstetrician attempts to dilate. He thinks the psychologic element is an important one. He related the history of one patient who presented no symptoms whatever of toxemic infection, there being no albuminuria or edema present, but who died shortly after the birth of her child. Another patient feared that her child might be born before the expiration of nine months from the date of her marriage, and was in a state of constant nervousness on this account. When labor finally occurred forceps had to be employed. The patient soon developed a condition of marked apathy and would pay no attention to her child. On six different occasions she had a convulsive seizure immediately after the physician's visit and just as he was leaving the house, but each immediately ceased upon his being recalled. The patient finally died, there having been no true symptoms whatever of toxemia.

DR. STOVER of Amsterdam, N. Y., said that the essential point in these cases is how surely and certainly, and how soon, can the condition of puerperal eclampsia be diagnosticated? He spoke in strong terms of the importance of a daily analysis of the urine. If called to see a patient late in the progress of the case the urinalysis may present entirely different features from that in the beginning. He knew of three cases occurring during the past three months in which the attending physician had waited for more marked symptoms to occur after albuminuria had developed, and each of the patients died. He thought the method of Etheridge of Chicago, probably a modification of that of Paget, of estimating the amount of urea, a very valuable one. The speaker referred to a case which came under his own observation in which but 500 grains of urea was excreted daily when there should have been 1300, the patient developing eclampsia.

The PRESIDENT said that he has found that the occurrence in females, during early life of exanthematous fevers,

has a marked influence upon subsequent renal insufficiency. In more than one instance he has been able to trace this insufficiency to an attack of scarlet fever, or diphtheria, occurring during childbirth. The question of puerperal eclampsia is no nearer to settlement than it was fifty years ago. The pathology of the condition is shrouded in darkness, and a step forward would be for the larger medical associations to institute a regular series of investigations with the hope of determining its cause.

In many of the worst cases premonitory symptoms are not present at all. In his opinion it is unwise to use haste in emptying the uterus, when this has been determined upon, as there is great danger of lacerating the parts. The question of the advisability of inducing premature labor in the case of a patient who, in a former gestation, had eclamptic attacks, but in whom at the time of the subsequent pregnancy no symptoms of toxemia were present, is an important one. He has completed the period of gestation in a number of cases of this sort, and thinks such action entirely justifiable, although it is not to be denied that a woman may go through a number of pregnancies normally before a second series of eclamptic attacks occur.

DR. LONGYEAR asked if the speaker advised the induction of premature labor under these circumstances if there were no symptoms whatever of renal insufficiency.

THE PRESIDENT replied in the affirmative and reported the history of a case in which he had practised it.

DR. RUFUS B. HALL of Cincinnati said that such a doctrine is an extremely dangerous one, and that he opposed it strongly. Merely because a woman at some previous time had had eclampsia was not sufficient reason for terminating gestation prematurely when no symptoms of toxemia were present.

In closing the discussion, DR. POTTER said the occurrence of albuminuria is a danger signal, but that decrease in the daily amount of urea excreted by a pregnant patient is still more valuable as a diagnostic sign. The question of the previous occurrence of exanthemata, referred to by Dr. Ross, was of extreme importance. The violent production of premature labor is never justifiable. If eclamptic attacks occur some time previous to labor, the physician may take time in emptying the uterus, but in the *intrapartum* variety, the cervix should be carefully dilated by means of a steel dilator and the hand, and, if necessary, forceps applied and the fetus delivered. He has accomplished this within three hours, when the cervix was rigid, without lacerating the tissues, and has saved the life of both mother and child.

THE PRESIDENT asked Dr. Hall if another physician came to him and said that he was afraid to have his wife go to term on account of having had eclampsia during a previous pregnancy, if he would advise terminating the course of gestation at once?

DR. HALL asked if the President meant for him to give such advice if no kidney lesion was then manifest, to which the President replied that the only symptom of kidney insufficiency was the presence of albumin in the urine. Dr. Hall replied that he would never give such advice under the circumstances, and thought such a course

unjustifiable. Symptoms of eclampsia must be present before he would advise interference, no matter what the previous history of the patient might be.

The next paper, entitled

PUERPERAL DIPHTHERIA,

was read by DR. H. W. LONGYEAR of Detroit. The essayist said that the Klebs-Loeffler bacillus is a potent factor in the etiology of puerperal infection, and cited six cases in proof of the statement. The diphtheritic character of each case was determined not only by clinical evidence, but by bacteriologic examination made by the bacteriologist of the Detroit Board of Health. Five of the patients recovered and one died, the one death being the only case in which antidiphtheritic serum was not used. He recommends bacteriologic examination in all cases of puerperal infection, condemns curetting in all cases where a membranous exudate is present, and the use of the antidiphtheritic serum, the intra-uterine application of a strong solution of iodine and carbolic acid at the beginning of treatment, drainage of the uterus by a tube, intra-uterine irrigation with antiseptic solutions, bi-hourly vaginal injections of hydrogen peroxid, and the usual supporting treatment with quinin and whisky. In mixed cases of Klebs-Loeffler and streptococcal infection he recommends, first, the use of the antidiphtheritic serum, and then, after twenty-four or forty-eight hours, the use of the anti-streptococcal serum.

He believes that the true character of this form of infection has not heretofore been recognized, but that it will be found to be more or less prevalent in all localities in which diphtheria exists, if sufficiently careful examinations are made. The physician and midwife are warned to use especial care in such localities, as the *post-partum* parturient canal furnishes the most favorable soil for the growth of the Klebs-Loeffler bacillus. In one of the cases reported, patches of pseudomembrane were present on the vaginal walls when none was present in the throat, and a bacteriologic examination of the membrane demonstrated diphtheria bacilli in great numbers. The speaker deplored the use of the sharp curette in cases in which toxic symptoms developed, as by its use new channels of infection are opened. The dull curette may be used with advantage in the hands of a skilled operator. If diphtheria prevails in the neighborhood of the patient it is wise not to wait until a bacteriologic examination reveals the exact nature of the infection, but to employ antidiphtheritic serum at once, as no harm will have been done if the condition proves to be due to invasion by streptococci. He is in favor, also, of washing out the vagina every two hours with two drams of full-strength hydrogen peroxid.

(To be continued.)

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held June 16, 1897.

THE President, CHARLES L. DANA, M.D., in the Chair.

DR. H. L. TAYLOR reported a case of transverse fracture of the femur above the knee-joint and exhibited a

skiagraph showing the lesion. The patient, a girl, eleven years of age, came to the Hospital for Ruptured and Crippled with a history of having fallen in such a way that the knee was doubled under her. She was helpless after the accident, and was confined in her bed for two weeks. When seen at the hospital, examination showed some swelling just above the joint, but there was very little tenderness. The angle of greatest extension was 155° , but flexion was normal in extent and free from spasm; from this fact it was evident that the knee-joint was unaffected. A ridge across the bone, not far above the joint, due to the forward projection of the upper fragment, could be felt distinctly and the diagnosis of diastasis of the lower epiphysis of the femur was made. A skiagraph of the injured limb showed that the injury was a simple transverse fracture of the lower end of the femur, considerably above the epiphyseal line, with impaction posteriorly. The case was reported to illustrate the value of the skiagraph in diagnosis.

DR. S. H. DESSAU remarked that in a recent discussion Professor Keen had expressed the opinion that not much reliance is to be placed on skiagraphs, especially in fractures of the radius, because they may not show the fracture well even when the surgical signs are very plain.

DR. E. S. PECK said he did not see any ground for such a positive statement on the part of Dr. Keen. Personally, the speaker had seen several very admirable pictures of fractures at the elbow-joint in which the small fractures of the condyles were very beautifully shown, and he considered skiagraphs of immense importance in diagnosis.

DR. J. H. FRUITNIGHT asked Dr. Taylor if separation at the epiphyseal line was of frequent occurrence.

DR. TAYLOR replied that it was extremely rare and that he had been interested to investigate the case reported on that account.

THE PRESIDENT said that the case brought to his mind one which was interesting in connection with skiagraphy. A woman about thirty years of age had come to his clinic suffering from a progressive atrophy of the hand and forearm. She was a dressmaker and had been forced to give up work on account of the disability. When she was ten or eleven years of age she had had a fall and sustained an injury of the elbow, but no fracture. She apparently got over this, and was perfectly well until four or five years before she presented herself at the clinic. At that time she began to notice a numbness of the little and ring fingers, and, later on, pain developed. When the patient was first seen the hand and forearm presented the appearance of a progressive muscular atrophy, the intrinsic muscles and ulnar distributions being affected. There was some anesthesia over the distribution of the nerve, however, and this, together with the absence of fibrillary contraction, made the speaker exclude progressive atrophy. As there was a history of an old injury, she was sent to Dr. B. F. Curtis, to see if he could find anything that would justify an operation. He reported that he was unable to discover anything which would account for the trouble, and advised that a skiagraph be made of the arm. Two pictures were taken from different points of view,

and these showed a distinct exostosis on the internal condyle. Dr. Curtis then cut down upon the ulnar nerve, and found that it had become pressed upon where it passed over the condyle, and that the constant irritation thus produced had caused a perineuritis and a fusiform enlargement of the nerve. He pulled the nerve out of its natural position back of the condyle and put it in front, so that it would no longer be irritated when the arm was flexed. Since the operation the patient had steadily improved, the pain and numbness have disappeared, and the woman has gone back to her work.

DR. TAYLOR said that the flexion of the leg in his case was due to the faulty position in which union had taken place before he saw the patient, and which could not be overcome without operation. He would advise that later the bone be divided by the chisel and the deformity corrected. In regard to Dr. Dessau's remark, the speaker had only that day seen a skiagraph of a forearm, showing the line of fracture with great distinctness.

DR. A. R. ROBINSON reported an unusual case of chicken-pox in an adult. The patient, a man of thirty, was first seen on Sunday, at which time only a few spots were visible. On Wednesday he was covered from head to foot with the eruption. The speaker asked if any of those present had ever seen a similar case.

DR. J. BLAKE WHITE said he had once seen a case of chicken-pox in an adult, and that the eruption strongly resembled that of smallpox. The umbilication was very marked.

DR. S. N. LEO remarked that he had seen cases of varioloid which resembled chicken-pox. He remembered one case in particular in which he had made a diagnosis of varioloid. The patient was a woman who kept a boarding-house. The case was reported to the Board of Health, and an inspector was sent to the house, who pronounced the disease chicken-pox. The patient placed the speaker in a very unpleasant position by threatening to sue him for making a wrong diagnosis, by reason of which her boarders had left her, thus causing her financial loss. Within a month he learned that two of the boarders, who had gone to different parts of the country upon leaving the house, had been attacked with a very severe form of varioloid. The speaker thought this case worthy of being placed upon record.

DR. FRUITNIGHT said that in children it was quite common to see chicken-pox which resembled smallpox. One is not apt to suspect chicken-pox in an adult, but the fact that it does occur at times should put us on our guard against making a diagnosis of smallpox too hastily.

DR. ROBINSON thought there would be no special difficulty in making a differential diagnosis if there were a sufficient number of lesions present. In the beginning of smallpox, one never sees vesicles such as are found in chicken-pox.

DR. E. S. PECK reported a case of mastoid disease in a child two years and two months old. The child had had a discharge from the right ear for eight weeks, and had been under the care of a homeopathic physician. During all this time, and in spite of the fact that at one time the child was in coma for several hours, neither

meningitis nor mastoid disease was suspected, and the child's temperature had not been taken for six weeks, although at that time it was 102° F. When the speaker first saw the child, the entire right side of the head, from the vertex to the jaw, was occupied by a swelling. The mastoid was immediately trephined, and from twenty to twenty-five drops of pus evacuated.

DR. R. A. MURRAY thought that patients with ear trouble should be warned of the risk they run in allowing it to go untreated, and referred to a case of a young man whom he knew to be suffering from ear disease, and who was seized with a convulsion and died of meningitis as a result of the former disease.

DR. PECK agreed with the preceding speaker and said he had a patient who for years had had ear trouble. It was a matter of astonishment to him that the mastoid had not become involved, for a probe could be passed up into the cells. The ear now gives but little trouble, probably because the patient has taken good care of herself in the way of avoiding cold and draughts.

DR. R. H. GREENE then read a paper, entitled,

SYPHILIS OF THE KIDNEY.

The paper was based upon the recorded results of the pathologic changes observed in the kidney after death in individuals suffering from syphilis at the time of death, or in whom syphilis was given as the cause of death. Few morbid changes are found *post-mortem* in the kidney which are distinctly indicative of syphilis, with the exception of syphilitic gummata, which are very rare. Syphilis, however, may be said to be directly or indirectly the cause of (1) parenchymatous nephritis; (2) interstitial nephritis; (3) gummatous nephritis, and (4) amyloid nephritis. One or more of these conditions may exist simultaneously, or follow each other, in an individual.

Parenchymatous nephritis occurs in syphilis as it does in other infectious diseases, and the symptoms do not differ. It is most apt to develop during the first few months while syphilitic lesions are present upon the skin or mucous membranes. The prognosis is favorable.

Interstitial nephritis may occur shortly after infection or late in the disease. Interstitial lesions of the kidney have been found in infants suffering from congenital syphilis. It usually affects both kidneys, and is very apt to occur in those affected with syphilis late in life.

Although gumma are rarely found in the kidney after death, there is reason to think that gummatous nephritis occurs more frequently than is generally supposed. Lobulated kidneys are sometimes found in which the lobulation is due to cicatricial bands which have formed after gummata have been absorbed. In such cases a differential diagnosis may be made from congenital lobulated kidney by the fact that in the former the capsule will be found adherent and dipping down into the cicatricial tissue. Gummatous nephritis, as a rule, attacks one kidney only, and is necessarily associated with some interstitial nephritis. Gummata of the kidney, like those in other parts of the body, are amenable to treatment, and the prognosis is good.

Amyloid nephritis is the most common form of renal

disease due to syphilis, and is often found associated with fatty degeneration. The diagnosis may be made by the presence in the urine of waxy casts and by the clinical symptoms.

The treatment of syphilis of the kidney should consist in the administration of the iodids and mercury. The latter should be cautiously prescribed, as in these cases salivation is especially liable to occur on account of the eliminative power of the kidneys being interfered with. The general health of the patient should also be looked after.

The following conclusions were arrived at:

1. That in a small proportion of cases, syphilis attacks, directly or indirectly, the kidneys, causing inflammation of the parenchyma, interstitial tissue, or giving rise to gumma and amyloid degeneration.

2. That any one of these conditions is seldom present by itself, but is usually associated with one or more of the others.

3. The syphilis shows in the various lesions of the kidney caused by it, except the interstitial variety, and even here, occasionally, a proneness to attack one kidney only.

4. It occasionally, by attacking the kidney, may give rise to symptoms which simulate malignant disease or renal calculi.

DISCUSSION.

DR. ROBINSON said he would not expect to find waxy casts in the urine as an indication of amyloid disease of the kidney. He also took exception to the term "syphilitic disease" as applied to the condition of any organ or tissue when there are no longer any syphilitic germs in the system. Syphilis, being a specific disease caused by an organism, can no longer exist when these organisms have left the body, therefore, any changes which occur subsequently should not be called "syphilitic." The term, "irritation lesion," he thought, was a better one to express the affections coming on after the active process had ceased. A sort of dyscrasia exists—there is an increase of the plasma cells and of the connective-tissue corpuscles—a pin scratch will not heal and white patches appear in the throat and mouth on the slightest provocation.

DR. WHITE said that little has been written about syphilis of the kidney *per se* because lesions are seldom found there. This is probably due to the fact that the kidney is an eliminative organ, constantly engaged in throwing off poisons and not absorbing them readily, and also because other organs are so much more prominently involved that the renal lesions are lost sight of. He agreed with the preceding speaker in regard to the application of the term "syphilitic disease" to lesions which follow syphilis. According to Dr. Otis, these should be called *sequelæ*.

DR. C. A. LEALE was of the opinion that the disease was not uncommon and that cases are often overlooked. He narrated the history of a woman, twenty-nine years of age, who had come to him recently with marked symptoms of kidney disease. She had been married two years and was three months pregnant, and had come to him to

have an abortion performed because her physician had told her she would die if allowed to go to full term. Upon examination she was found to be covered with a syphilitic eruption and showed the usual manifestations of the disease. The speaker considered the kidney trouble directly due to the action of the syphilitic poison and the patient was now under treatment for this disease. He also mentioned another case in which labor was brought on at the eighth month on account of the kidney symptoms. The baby lived and developed syphilis within two weeks. At the age of twelve, the child suddenly became blind, remained so for some time, and, finally, regained its sight under antisyphilitic treatment.

DR. FRANK GRAUER did not believe the disease was of common occurrence. He had seen only three cases of so-called syphilitic gumma of the kidney in the thousand autopsies which he had witnessed. One was that of a young man who had entered Bellevue Hospital with a history of meningitis. A diffuse meningitis with gumma was found, and also a gummatous growth in the kidney. In regard to waxy degeneration being generally confined to one kidney, the speaker said the disease was bilateral in all the cases he had ever seen and was caused usually by tuberculosis or syphilis.

DR. R. A. MURRAY said that syphilis of the kidney was undoubtedly one of the causes of hematuria, and mentioned two cases in which the latter was relieved by the use of inunctions.

DR. FRUITNIGHT referred to a case of hematuria occurring in a young man who had syphilis. Bacteriologic examination of the urine showed that he had tuberculosis.

DR. GREENE, in closing, said he agreed perfectly with all Dr. Robinson had said in regard to the term "syphilitic disease," in fact, he stated in the beginning of his paper that it dealt with diseases of the kidney of which syphilis was the direct or indirect cause. He, however, thought the dyscrasia which follows syphilis could best be described by the term "fibrosis." Gumma is generally considered as syphilis in its active state, although it is a disputed point whether or not the secretion of gumma will give rise to the active disease. It is, in all probability, an intermediate state.

In regard to syphilis showing itself by amyloid changes in one kidney only, the speaker said his views were based upon autopsic observations made on persons who had died of syphilis. Most of these observations had been made by the Germans, notably E. Wagner, who mentioned a number of cases of syphilis of the kidney in which only one of the organs was affected. The speaker expressed the opinion that the same changes might be found as a result of long-continued suppuration or of tuberculosis.

CORRESPONDENCE.

OXYTUBERCULIN.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Replying to a letter addressed to you by S. Bookman, Ph.D., M.A., which was published in THE MEDICAL NEWS of July 31st, I very much regret the per-

sonally aggressive manner in which it was written. Such a spirit should never be observed in scientific work, and I shall therefore act as if it did not exist.

With regard to the subject matter itself, I will state that in the paper read before the California State Medical Society I avoided all theoretic discussion as far as I could, and limited myself to a statement of facts as observed by me. The lecture was more historic than argumentative. I referred to the observation of surgeons in cases of laparotomy for tuberculous peritonitis, because it was these often recorded results that led to a theory. Following this theory, a line of investigation was carried out and the facts observed and recorded. It is provisionally of little importance whether the theory which led to the plan of treatment be correct or not; that which is of the utmost significance, however, is: Are the facts correct or has there been an error in the methods? As I stated, "I simply desire to present to you the evidence that I have thus far collected, and to ask you whether you consider it sufficient to warrant further investigation by me and by yourselves in the same direction. The work is not presented as a finished task."

The missing evidence has been far more forcibly and clearly referred to in the editorial of THE NEWS of July 10th than in the letter of Dr. Bookman. The investigation is by no means so simple a matter as he seems to think. A complete investigation would have to be conducted in three directions: (1) Bacteriologic; (2) experimental; (3) clinical. I believe I have established my thesis absolutely with regard to the specifically bactericidal action of oxytuberculin. The experiments have been so frequently repeated and have been watched so carefully by so many of my colleagues that there can be no possibility of error. In the clinical department I have been as careful and as skeptical as possible. My patients have been observed by other physicians wherever it has been possible before, during, and after treatment. Their mode of life has not been changed, they have not received any other medicine except a mixture of codein and syrup of wild cherry now and then when the cough has been very harassing. A few, who had contracted malaria with enlarged spleen, received quinin. The results have come so rapidly in early cases that it was absolutely impossible to explain them in any other manner than by ascribing a specific effect to the oxytuberculin. In the laryngeal cases the disappearance of the trouble has been watched by laryngeal specialists. I have left the second method of investigation, the experimental, to others who may be better equipped for the purpose. There are two lines that would have to be followed in such research:

1. The effect of the oxytuberculin upon the toxin.
2. The effect upon the pathologic condition.

I would suggest that it first be determined, whether or not the oxytuberculin will inhibit the action of tuberculin; and, second, whether it will prevent the development of the injected germ in the guinea-pig, or bring about its absorption after it has developed.

More space than can be allowed me in this response would be necessary to cover the whole ground, I simply desire to state that I have placed my evidence, bacterio-

logic and clinical, before the profession and desire that it be investigated skeptically, but honestly. Should my observations be found to be incorrect, no one would acknowledge the error more readily than I, for what we desire is only the truth.

J. O. HIRSCHFELDER, M.D.

SAN FRANCISCO, CAL., August 3, 1897.

REPLY TO DR. UPSHUR.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: In THE MEDICAL NEWS of June 24th, I reproduced a portion of your abstract of Dr. Upshur's paper and criticised his invidious comparison of the reports of honorable physicians with the "testimonials" of the dupes and touts of charlatans so freely given to the shameless venders of "cancer cures" and "kidney cures," *sui generis*. I thought the Doctor would see at once that his language was grossly insulting, not only to every physician who had reported the results he had obtained with the "Woodbridge method" of treating typhoid fever, but to every member of the medical profession whose *esprit de corps* makes the word of a medical man on a medical topic infinitely more valuable than that of any layman, and under no circumstances to be mentioned in connection with, compared with, or even contrasted to "the testimonials" of the medicaster and his *gobemouche*, and that he might see the gravity of his offense in its true light, I stated that there had been reported 7857 cases of typhoid fever treated by the method under consideration, with 150 deaths—a death-rate of 1.91 per cent. Instead of accepting my hint and, in the chivalrous spirit for which the gentlemen of his State are noted, promptly apologizing, Dr. Upshur further transgresses by attempting to excuse his utterly unjustifiable language by referring readers to my paper in the *Journal of the American Medical Association* of July 10th, in which are published a few extracts from reports received since I read my paper before the Ohio State Medical Society in May last.

The Doctor says: "I have no personal abuse for Dr. Woodbridge"; but why should others suffer for my offense? I am the guilty one. Why should he let me escape, and heap such infamy on the brave and noble physicians who so courageously volunteered in defense of a stranger in the hour of adversity? But, Mr. Editor, there have been many amusing incidents connected with this old controversy, in which this new knight has just broken his lance; but his letter will challenge comparison with the best of them all. I have been accused of having *said* and *done* many things which were foreign to my notions and in conflict with my dearest theories. Debators and dissertationists have wasted words and ink in frantic efforts to prove that statements which I have *never* made should never have been uttered, and that claims which I have *never* advanced should never have been made. But the palm of victory belongs to the writer who "begs space for correction" of my "inaccurate statements" in the current number (July 31st) of THE MEDICAL NEWS, who says: "I protest that I shall not be misrepresented as having 'sanctioned' the use of phenacetin," etc.; who says, "Why does he take part of a sentence and make

me 'sanction',' etc., and who then launches out in an effort to prove that he does not use or advise the use of phenacetin in the treatment of typhoid fever.

Now I protest that in the article which he is correcting I was *not* "inaccurate"; I did *not* misrepresent him; I did *not* make him "sanction the use of a remedy" which he had not himself "sanctioned." If the words "such preparations as phenacetin, etc., may be used in small doses," does not *sanction* the use of phenacetin, what were they put in the paper for? In this, Dr. Upshur seems to be quibbling in order to distract attention from the insult he has offered the medical profession and for which he will, if he be a gentleman, avail himself of the earliest possible opportunity to apologize.

The closing sentence of Dr. Upshur's letter is a *non sequitur*. The treatment which will give, in the safest and easiest way, the largest percentage of recoveries, with the smallest percentage of deaths, as well as the shortest duration of the mildest illness and the quickest restoration to the most perfect health, will need no other commendation.

That all of these results are best attained in the disease indicated by the method of treatment under consideration, is amply proven by the commendations of the physicians who have used it and by the following statistics: Number of cases of typhoid treated to date, 8639; number of deaths, 161; death-rate, 1.85 per cent.; average duration of illness in 5511 cases, 12.9 days.

JOHN ELIOT WOODBRIDGE.

CLEVELAND, OHIO, August 10, 1897.

REVIEWS.

TRANSACTIONS OF THE EIGHTEENTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION. Held in the City of Pittsburg, Pa., May 14, 15, and 16, 1896. New York: D. Appleton & Company, 1897.

The extensive program of this meeting, comprising as it does thirty-four papers, not including the theses of the candidates for membership, proves, in the words of the President's address, that it is quite possible to have for a scientific organization a congress of the first class in a city of the second class.

Among the papers of general interest, that of Dr. Carl Leiter on "Prophylaxis of Nasal Catarrh" is worthy of notice as a valuable contribution to a subject of great practical importance. As indicated in his remarks, cleanliness, not only of the whole body, but of the nasal cavities in particular, whether a cold in the head is present or not, is the primal and most important prophylactic measure which can and should be instituted to prevent recurrence of acute coryza; to prevent, finally, systemic infection by ingestion of putrefactive products. As important as this nasal cleansing, is the proper feeding and clothing of children, so that overheating of the general system may be avoided, and the skin, especially around the neck and arms, should be so hardened by cold-water applications, in the form of sponging morn-

ing and night, that moderate exposure will not readily give rise to acute coryza. The suggestions deserve to be followed, even if we may be inclined to consider the author's judgment on the condition of the American child as too severe. There will be some dissent from the generalization that the children are, as a rule, too much clothed, too much confined indoors, and overfed with heat-producing food, so that when they leave the nursery they are mere hot-house plants, and that it takes a long course of out-door sports with boys to inure them to exposure, with a number of the after serious effects of exposure, upon the respiratory organs in particular, to make them strong and healthy.

The relation of acute diseases of the nose and throat to disorders of digestion is well treated by Dr. Moreau R. Brown, while Dr. T. R. French supplements this paper with a consideration of chronic conditions of this sort and their results. The sequelæ of syphilis, nasal, pharyngeal, and laryngeal, and their treatment, are discussed respectively by Drs. C. H. Knight, J. E. H. Nichols, and W. K. Simpson.

THE DISEASES OF THE STOMACH. BY DR. C. A. EWALD, Extraordinary Professor of Medicine at the University of Berlin. Translated and edited by MORRIS MANGES, A.M., M.D., Assistant Visiting Physician to Mount Sinai Hospital; Lecturer on General Medicine at the New York Polyclinic. Second revised and enlarged edition. New York: D. Appleton & Co., 1897.

THE recent great advances in the knowledge of diseases of the alimentary tract, particularly of the stomach, have necessitated a new English edition of Ewald's book. This is rendered more readable by the abandonment of the style of the first edition, in which the chapters were in the form of lectures.

We note particularly the greater minuteness in the details of the examination of stomach contents; the recommendation of Uffelmann's test for lactic acid and that of Töpfer for free hydrochloric acid, and the doubt expressed as to the merit of the biuret reaction. Meltzer's experiments showing the non-contraction of the fundus of the stomach to the faradic current are thoroughly discussed, and the conclusion that we cannot judge why gastric faradization benefits some people is reached. The author and the translator disagree as to the value of palpation of the stomach tube *in situ*, the former doubting its worth, the latter believing it to have merit. The advantages and disadvantages of gastroduaphony are thoroughly considered. Turck's work on the infection of the gastric mucous membrane from the mouth and pharynx is referred to.

The book is thoroughly modern and is a safe and sound exposition of the diseases of the stomach. The editing is splendidly done and the English is above reproach. The book is well printed and well bound.

PRACTICAL PATHOLOGY FOR STUDENTS AND PHYSICIANS. BY ALDRED SCOTT WARTHIN, Ph.D., M.D., Instructor in Pathology, University of Michigan. A Manual of Laboratory and Post-mortem Technic, designed especially for the use of Junior and Senior Stu-

dents in Pathology at the University of Michigan. Ann Arbor, Michigan: George Wahr, 1897.

No apology is needed for a good, reliable and practical book in English on laboratory technic, but when such a book is intended as a guide to the student, it must at least be accurate. This is not always the case in the work before us, which is mostly a compilation of the more important and commoner methods of laboratory technic.

Part I. deals with the directions for performing *post-mortem* examinations and occupies one-half of the book. Rokitsansky's method for opening the heart is given. This is undoubtedly the best method for the examination of this organ *in situ*, but a few well-chosen illustrations would be of great benefit to enable the student to understand this procedure. The directions given for obtaining uterine curettings is entirely out of place in a book of this kind.

In Part II. the student is told how to preserve, fix, harden, imbed, cut, and stain specimens, and the various methods of examining bacteria in fluids and in cut sections are given. The specific stains for inflammations and degenerations are also stated, and a chapter is devoted to the examination of the blood. Some of the methods are not clearly stated, as for instance, the mounting of paraffin sections. On one page we are told that the Klebs-Löffler bacillus is stained by Gram's method; further on, that it is not, and the student is left to decide the matter. This and other errors should not have crept in. However, the book may be consulted for many formulas and methods of daily use.

THERAPEUTIC HINTS.

Nutrient Enemata.—In many instances a nutrient enema composed only of whisky and peptonized milk will not be retained by the patient. A better combination, and one which will give more satisfactory results, is the following:

R	Beef peptinoids	.	.	.	.	3 ii
	Yolk of egg	.	.	.	.	No. 1
	Whisky	.	.	.	.	3 ss
	Tr. opii	.	.	.	.	m. v-x
	Salt. q. s.	.	.	.	.	
	Peptonized milk, q. s. ad.	.	.	.	.	3 vi.

A Sedative Syrup.—An excellent sedative combination in cases of insomnia or mild delirium, is the following:

R	Chloralis	.	.	.	.	3 iss
	Sodii brom.	.	.	.	.	3 iii
	Ext. cannabis ind.	} aa	.	.	.	gr. iss
	Ext. hyoscyami		.	.	.	
	Syr. simp., q. s. ad.	.	.	.	.	3 iii.

M. Sig. Tablespoonful, to be repeated if necessary after an interval of four hours.

A Palatable Method of Administering Castor Oil.—In the case of children who object to taking castor oil the dose may be made much less disagreeable if the oil is combined with glycerin and tincture of cardamon, as follows:

R	Ol. ricini	.	.	.	.	3 ss
	Glycerini	.	.	.	.	3 iii
	Tr. cardamonii comp.	.	.	.	.	3 i.

M. Sig. One dose.

ORIGINAL ARTICLES.

THE NEED OF AN IMPROVED TECHNIC IN THE MANUFACTURE OF KOCH'S "T.R." TUBERCULIN.

By E. L. TRUDEAU, M.D.,
AND
E. R. BALDWIN, M.D.,
OF SARANAC LAKE, N. Y.

SINCE the announcement by Professor Robert Koch, last April, of a "New Tuberculin," by which he claims to immunize guinea-pigs against subsequent virulent inoculations with tubercle bacilli, and even to cure these animals of the disease, provided the treatment is begun within two weeks after the inoculation, some experience has already been gained with it by us at the Saranac Laboratory which shows evident imperfections of the substance as at present manufactured, and indicates the possibility of serious objections to its use in human beings until these shall have been overcome. Disclaiming any intention of criticising the value of the original and all important facts bearing on the production of artificial immunity set forth in Koch's recent paper, the present notes are merely confined to that part of our experience which relates to the character of the product as at present manufactured and sold; and briefly presents evidence thus far obtained which bears on the nature and defects of the preparation itself.

A careful reader, familiar with the technical difficulties involved in such work as the preparation of the new tuberculin, must be impressed at once with two facts: (1) The extreme difficulty of preventing accidental contaminations of the substance in the somewhat complicated process of manufacture without the use of heat or antiseptics. (2) The evident uncertainty of separating by centrifugation alone the uncrushed and still living tubercle bacilli from the fluid in which they are suspended. Our experience with Koch's "T. R." tuberculin would indicate that neither of these difficulties appears to have been as yet entirely overcome by the present manufacturers; and as the first requirement of an injection fluid intended to produce immunity is that it should be entirely free from danger, we have felt it our duty to make known such of our observations as relate to this point.

In all we have received seventy-six vials of the new tuberculin (designated "T. R.") and the fol-

lowing list indicates the dates of manufacture and the condition on arrival, arranged in the order of their coming:

No. of Vials.	Cork-stoppered.	Contamination.
5	6-4-'97	Not apparent to eye, but on culture and microscopic test all show various yeast-like growths. No attempts made to identify them.
5	6-4-'97	
10	12-4-'97	
5	12-4-'97	
1	3-5-'97	
2	1-6-'97	
	Glass-stoppered.	
1	15-6-'97	Apparent to eye; mould.
2	15-6-'97	Apparently sterile; confirmed by culture.
5	25-6-'97	
30	10-7-'97	Five contaminated; mould; twenty-five sterile.
10	10-7-'97	One contaminated; mould; nine sterile.

We used the first five vials on guinea-pigs at once, though not regarding it as a scientific experiment. The injections of this contaminated "T. R." tuberculin under the skin of guinea-pigs produced (except in one instance, to be referred to later) only temporary induration, which soon disappeared and was never followed by abscesses or any immediate constitutional disturbance in these animals. These observations seemed to indicate that the contaminating organisms found in "T. R." were non-pathogenic, that the only harm resulting from their presence was that the immunizing properties of the fluid might be impaired by their growth in it; and that with a little care in the selection of sterile bottles with the application of the culture-test to each, the use of the preparation in the human subject was perfectly permissible.

The possibility that the fluid contained tubercle bacilli was a much more serious matter. We made repeated microscopic examinations of the various specimens received at different times with negative results. Recently we centrifugated the contents of one or two bottles at a time and made microscopic examination of the sediment. In this sediment about six or eight well-stained tubercle bacilli were found in each cover-glass with little difficulty. That these tubercle bacilli might be living seems demonstrated by the following observations:

While attempting to test for ourselves the immunizing properties of Koch's "T. R." on guinea-pigs, we had under observation five animals, which, since we first received the fluid, on May 7th, had been injected according to Koch's directions, with increasing doses of "T. R." The first lot of tuberculin was exhausted after four doses, aggregating four mil-

ligrams of solid substance for each pig, and a long interruption in the injections was caused by a considerable delay in receiving enough sterile tuberculin for this purpose; but they were resumed on July 31st and have been regularly given since that date. On August 4th, we noted that while four of the animals had held their weight and seemed in no way injuriously affected by the treatment—though in one of these a very small inguinal lymph-node could be detected—the fifth and smallest animal had lost ten grams in weight and looked ill. This pig presented a small and steadily increasing swelling at the site of one of the injections, and one of the lymph-nodes in the groin was much enlarged. On examination, the subcutaneous swelling proved to be a cheesy abscess in which were found tubercle bacilli. The lymph-node itself was caseous, and its cheesy detritus contained also numerous tubercle bacilli. Plants on gelatine and in bouillon made from the cheesy pus taken from the abscess and node remained sterile, and proved that no living organisms other than tubercle bacilli were present. All the instruments used in making the “T. R.” injections, as well as the syringe, which had never before been used for inoculations, were always thoroughly sterilized by heat and the skin of the animals washed with carbolic solution before the injections were made, so that accidental infection of the animal may fairly be excluded. The only conclusion to be reached is, that one of the five animals developed tuberculosis as the result of inoculation with the living tubercle bacilli contained in the “T. R.” injections.

During the past three months we have been able to repeat at the Saranac Laboratory Koch's recently published method relating to the immunizing fluid, and to carry through several times, with our own virulent cultures, the processes of manufacture; following closely the rather meager details given by its inventor. All the technical difficulties encountered in this rather complicated process have apparently been overcome, though with much trouble, with the exception that we never have been able to satisfy ourselves that our “T. R.” did not contain some tubercle bacilli. Koch states that three-quarters of an hour centrifugation with an apparatus reaching a speed of 4000 revolutions a minute will throw down all the bacilli. We have used an electric centrifuge constructed with aluminum arms, made as light as possible, and operated *in vacuo*. From this we have obtained a much higher speed than 4000 revolutions a minute, without feeling quite certain that after whirling an hour the supernatant fluid, if carefully drawn off only to two-thirds the depth of the tube, was absolutely free from tubercle bacilli. We succeeded, however, in practically excluding them by revolving the centrifuge at

a speed of 1300 per minute in three periods of twelve hours each. After each period the supernatant fluid was pipetted two-thirds the depth, with a capillary tube and transferred to fresh tubes. The last sediment occasionally contained a stray bacillus. Whether Koch's experience with his immunizing fluid, and his confidence in the production of a strong immunity in the patient as a result of its injection, have been such as to make him feel that the presence of living tubercle bacilli in the new tuberculin can be disregarded on the ground that the introduction under the skin of a few more or less bacilli in patients already tuberculous is not a source of danger to them, is of course unknown to us. Without any personal or more general experience, however, of the ultimate immunizing effects of this method, it would seem that unless by repeated centrifugation or some other means we can rid the new tuberculin entirely of living tubercle bacilli, we are hardly warranted in applying it as yet to the treatment of human beings.

TUBERCULOSIS OF THE MESENTERIC LYMPH-GLANDS AND ITS TREATMENT BY ABDOMINAL SECTION.*

BY REUBEN PETERSON, M.D.,

OF GRAND RAPIDS, MICH.;

PROFESSOR OF GYNECOLOGY, CHICAGO POST-GRADUATE MEDICAL SCHOOL; ATTENDING GYNECOLOGIST TO BUTTERWORTH HOSPITAL.

THE importance of tuberculous diseases of the mesenteric lymph-glands as a causative factor in the production of other forms of tuberculosis seems to have been somewhat lost sight of during the past few years. While undoubtedly, under the name of *tabes mesenterica* or *abdominal scrofula*, the older writers included many forms of peritoneal and intestinal tuberculosis, there is considerable evidence to show that primary tuberculous disease of the mesenteric glands is by no means uncommon. These glands, like the cervical and bronchial, are frequently found on *post-mortem* examination to be the seat of tubercular changes.

In 107 autopsies on patients dying from abdominal tuberculosis, König¹ found the mesenteric glands involved in 44 per cent. Holt,² in 109 *post-mortem* examinations on tuberculous children, found tuberculosis of these glands in 35 per cent. Hecker,³ in 100 consecutive autopsies of children, found tuberculosis as a cause of death 27 times. The lymph-glands were affected in 92 per cent. of the cases, the bronchial twice as often as the mesenteric.

These statistics include secondary as well as primary infection, as they were compiled from examinations of subjects who had died of advanced tuber-

* Candidate's paper presented for admission to membership in the American Gynecological Society at its Twenty-second Annual Meeting, held at Washington, D. C., May 4, 5, and 6, 1897.

culous disease; but they are important as showing the frequency with which the mesenteric glands may be infected. Moreover, the percentage of cases in which the lymph-nodes are the seat of tuberculosis is much greater than is the case with tuberculous intestinal disease, and would lead to the conclusion that Holt⁴ and others are in error in their claim that tuberculous mesenteric disease is usually secondary to tuberculous ulceration of the intestinal tract. More to the point, in the consideration of the primary form of this tuberculous glandular affection, are the statistics of Woodhead,⁵ who found the mesenteric glands affected in 100 out of 127 cases of tuberculosis in children, in 14 of which there were no tubercles in other parts of the body. Carr⁶ found the mesenteric glands alone affected five times in 120 children. In 70 cases various lymph-glands were diseased.

Osler,⁷ speaking of the tubercular involvement of the mesenteric glands, says that these cases are commonly spoken of as consumption of the bowels, but in a majority of them the intestines do not present tuberculous lesions. Rotch⁸ asserts that "in the majority of cases tubercular ileocolitis is secondary to tuberculosis elsewhere, and, in such cases, frequently follows tuberculosis of the mesenteric glands."

Indolent tuberculous mesenteric glands are not infrequently found in children who have died of acute disease, and who present no other evidence of tuberculosis.⁹⁻¹⁰ Orth¹¹ and Wesener state that the mesenteric glands are occasionally found infected in animals fed with tubercular tissue, without the mucous membrane showing any tuberculous lesion. It is a well-known clinical fact that children affected with non-tuberculous intestinal catarrh are particularly prone to tuberculosis of the mesenteric glands. As in the case of tuberculous cervical glands, the infection probably is produced by the bacilli passing through the mucous membrane before they have caused any visible lesion at the point of entrance.

Delafield¹² has reported a case in which death occurred five months after the cervical glands near the angle of the jaw were noticed to be enlarged. The autopsy revealed, in addition to other tuberculous lesions, a calcification and cheesy degeneration of the mesenteric glands. The calcification pointed to an early infection and subsequent recurrence in the same glands. Rotch¹³ reports the case of an infant, nineteen months old, who was seized with vomiting and diarrhea, and died in ten days. The autopsy showed enlargement of the mesenteric glands. Acute general peritonitis had resulted from the extension of the cheesy process in two of these glands through the peritoneum. Owen¹⁴ records a case where celiotomy revealed only a tuberculous inflammatory condition of

the mesenteric glands. Most of them were of the size of horse-beans. None had broken down. There was no miliary infiltration of the peritoneum, and no ascites. Recovery was rapid and complete.

Lucas,¹⁵ Councilman,¹⁶ Gairdner,¹⁷ Bamburgh,¹⁸ and Besnier¹⁹ have reported cases of primary involvement of the mesenteric glands. It is to be expected that clinical observations of this fact would be chiefly limited to acute forms of the disease, as the chronic form, unless giving rise to marked symptoms or to tumors of large size, would not be diagnosticated except accidentally by operation.

It is even probable that tuberculous disease of the mesenteric glands, as elsewhere in the body, may be congenital.²⁰ Considerable evidence is accumulating to prove the correctness of Baumgarten's views that the tubercular virus may be transmitted, though the disease may not appear till some time afterward. It has been shown that tuberculosis may exist in very young infants, and even in the fetus. Frobelius,²¹ in 16,581 autopsies on sucklings, found 416 with tuberculous lesions. Tuberculosis of the placenta has been demonstrated in a few cases, and Schmorl and Kockel²² found bacilli in the fetal tissues in one of three such cases. Armanni²³ produced tuberculosis in the guinea-pig by inoculations of the organs of the stillborn child of a tuberculous mother. Warthin²⁴ has reported an interesting and instructive case of extra-uterine gestation associated with tuberculosis of the tubes, placenta, and fetus. Cases of tuberculosis in very young infants are not uncommon, and this, with the fact that the lesions usually are in the deep-seated organs, lends strength to the theory of congenital and latent tuberculosis.

Mafucci²⁵ has shown experimentally that "tubercle bacilli inoculated into hens' eggs before incubation remain quiescent during the period of embryonic development, but cause the death of most of the chicks from tuberculosis in three weeks to four and one-half months after birth." Councilman²⁶ states that bacteria may remain alive, but quiescent, for long periods of time within the body, and then their pathogenic energies may be stimulated into activity through trauma or some other cause. The question of inherited and latent tuberculosis must evidently be attended by great difficulties, owing to the uncertainty connected with the finding of the tubercle bacilli in the fetal mass when no visible lesions are present. We must rest content for the present with the knowledge that the bacilli may be transmitted from mother to fetus, and after birth produce tuberculous lesions. Future investigations must determine the frequency with which this occurs and its importance as an explanation of the tuberculosis of early life.

The following cases observed by the writer are undoubted instances of primary tuberculosis of the mesenteric glands:

CASE I.—Mrs. M. G., thirty years of age. A patient of Dr. Eugene Boise. Presented a history of indefinite abdominal pain coming on during her second pregnancy. She grew worse after the birth of her child, had chills and fever, and lost considerable flesh. The abdomen was distended and very tender, but there was no ascites and the pelvis presented no abnormality. There was no diarrhea. The patient was brought to the hospital and an exploratory celiotomy performed February 3, 1891. The mesenteric glands were found enlarged, varying in size from a pea to an English walnut. With the exception of a distended condition of the intestines, the abdominal organs were perfectly normal. None of the glands was removed for microscopic examination, as the tuberculous character of the glandular tumors was not questioned, and the abdomen was closed. The patient recovered from the operation, has borne a healthy child since, and to-day is in good health.

CASE II.—The following abstract of this case is made for the purpose of this paper: "The patient is a delicate child, eleven years old. The family history is markedly tuberculous, three paternal aunts and one paternal uncle having died of phthisis. One maternal aunt also died at an early age of an acute form of the disease. While the parents never have manifested any tuberculous symptoms, they are people of weak constitutions and have little power of resistance. The elder sister, a girl of eighteen, has been an invalid during the past two years. Last May, in consultation, I saw another sister, aged twelve, who was in the last stages of general tuberculosis. This little patient had had abdominal pain for more than six years of such severity as to interfere with her studies and play. The abdominal symptoms became more marked three months before death. Ascites and general infection followed. Some few weeks after her death I was asked to see the present patient, whom the family were positive was developing the same symptoms which had proved fatal in her sister's case. A most careful examination failed to reveal any localized tuberculous process. The prominent symptoms were indefinite abdominal pain, a troublesome nausea and general malaise. There had never been any irregularity of the bowels. Tonic treatment proved of little avail except in remedying the marked anemic condition. January 11th I saw her again after an interval of several months. Upon examination I found a localized tenderness over an area as large as the palm of the hand, situated two inches to the right and an inch above the umbilicus. Otherwise the examination was negative.

"The family was advised that the localized abdominal tenderness was probably due to a tuberculous process of some kind, and an exploratory celiotomy was advised. This was performed at Butterworth Hospital three days later. An inch-and-a-half incision was made in the median line midway

between the pubes and umbilicus. The exploring finger, carried to the site of the abdominal tenderness, detected a chain of enlarged glands in the mesentery of the small intestine. These glands averaged $1\frac{1}{2}$ cm. long by 1 cm. wide. They were freely movable under the peritoneum. A small loop of gut, together with the mesentery, was brought outside and one of the glands removed for microscopic examination, and the peritoneal incision brought together by fine catgut. The enlarged glands were distributed throughout the mesentery, but nowhere were they in such numbers as at the place just described. The intestines appeared normal, as did the appendix. The following is the report of the hospital's pathologist, Dr. J. B. Whinery:

"Enlarged gland from the mesentery, hardened in absolute alcohol and imbedded in paraffin. Cut sections stained for tubercle bacilli. Carbofuchsin method. Examination negative. Sections stained with lithium carmine and picric acid showed proliferation of glandular tissue, occasional groups of cells, probably of early tubercular formation. Giant cells absent. No caseation or breaking down of tissue."

CASE III.—Miss G. H., aged seventeen, sister of patient described in Case II. Has always been a delicate child. Although ambitious and anxious to excel in her studies, she has been obliged to give them up because of poor health. She began to experience indefinite abdominal pain some two years ago. During the past year she has been much prostrated by the pain, and recently a localized tenderness developed a little to the right and above the navel. She has never had diarrhea. With the exception of the area of localized tenderness the abdomen presented no abnormality. Examination of the lungs and sputum was negative. Tonic treatment proved valueless, and the patient continued to lose flesh and strength. After the marked improvement following celiotomy in her sister's case, the patient and family asked that the same line of treatment be instituted for her relief. Accordingly, the abdomen was opened January 28, 1897, by a small incision midway between the umbilicus and pubes. There existed the same enlargement of the mesenteric glands, situated directly under the area of localized tenderness. These glands were slightly larger than those in Case II., averaging 2 cm. long by $1\frac{1}{2}$ cm. wide. Four were enucleated for microscopic examination, and the incision in the peritoneum closed with catgut. As in Case II., except the enlarged glands, the abdomen was perfectly normal. The abdominal incision healed by first intention, the patient made a good recovery, and left the hospital at the end of two weeks. Microscopic examination of the removed glands showed:

"Size, $1\frac{1}{2}$ c.m. by 2 c.m.; firm. Examination conducted as in Case II. Proliferation of small round cells, with here and there a group of endothelioid cells. No giant cells present. No caseation. Tubercle bacilli present, but very scarce."

The ultimate result of the operations upon these two patients can only be conjectured. They are

not reported as cures, but merely as examples of tuberculosis confined to the mesenteric glands, presenting symptoms which were temporarily relieved by operation. Both these patients at the present writing (Aug. 13, 1897) show marked local and general improvement. The abdominal pains have entirely ceased. In Case II. there is no localized tenderness, while in Case III. it is only elicited by deep pressure.

In view of the localized abdominal tenderness present in these two cases, it is possible that even small enlargements of the mesenteric glands may give rise to symptoms which may lead to a diagnosis of tuberculous lesions. The operation in Case II. was performed for abdominal pain and tenderness localized to the right and above the umbilicus. Tuberculosis of the peritoneum or omentum was suspected from a knowledge of the origin and course of the disease causing the sister's death. The similarity of the symptoms presented in Case III. led to the diagnosis of tuberculous mesenteric disease, which subsequent operation proved to be correct.

While the history of the cases of these three sisters is, perhaps, unique, rendering the diagnosis in Case III. comparatively easy, it is possible that closer attention paid to obscure abdominal pain and localized tenderness in young children with a tuberculous family history, will lead to the diagnosis of tuberculosis of the mesenteric glands before the disease has advanced to a point where operative treatment holds forth but little hope of recovery.

Thompson,²⁸ in speaking of the diagnosis of *tabes mesenterica*, after stating that the pathognomonic sign of the disease is the presence of tumors palpable through the abdomen, and that this sign is only present in advanced stages of the disease, says "the patient affected by *tabes mesenterica* complains almost continually of pain, the seat of which is never acute nor analogous to colicky pains unless the *tabes* is accompanied by inflammation or ulceration of the intestinal canal. The pain is not superficial, and is not accompanied, like that of chronic peritonitis, by considerable distention of the belly, vomiting, and dulness, nor is it attended, like that of intestinal ulcers, by diarrhea. The pain in *tabes* often continues during a very long time, and sometimes for years without any other remarkable symptoms presenting themselves."

When the disease has progressed still further, and general involvement and enlargement of the glands ensues, the symptoms become more marked. The nutrition of the patient may be seriously interfered with from the pressure of the tumors upon the lacteals and thoracic duct. Tympanites, diarrhea, and peritonitis, with or without agglutination of the

bowels, are quite constant accompaniments of the later stages of the disease. From a fusion of the glands, very large tumors may be produced, growths the size of a child's head having been reported.²⁹

The pathologic changes occurring in tuberculous mesenteric glands are the same as in other lymph-nodes of the body, save that the glands in this locality seem rather more prone to calcification than elsewhere. Caseation is not infrequent, and explains the not uncommon association of tuberculous peritonitis with mesenteric glandular tuberculosis. Instances of the extension of the tuberculous glandular lesions to the peritoneum have already been cited. The extension is oftenest by contiguity through the peritoneum, as a localized peritonitis usually attends a caseous mesenteric gland. It is possible, however, for the bacilli to be carried to the peritoneum by the reversed lymphatic currents which are known to exist in these vessels. Whatever may be the mode of the peritoneal infection, the danger of such infection is considerable, and its occurrence means the lessening of the patient's chances for ultimate recovery.

In a recent elaborate and excellent article, Vaughan³⁰ estimates that while one-third of all men are affected, at some period of their lives, with some form of tuberculosis, only one-seventh die from the disease. This would show that tuberculosis is far from being the fatal disease it is supposed. Vaughan urges the importance of early diagnosis while tuberculosis is an unmixed infection. In this stage he believes it to be one of the most easily curable of bacterial diseases. He claims that tuberculosis begins as a local disease, and if the resistance of the tissues can be increased, extension of the disease does not occur, and it dies out or becomes localized.

In the case of tuberculous mesenteric glandular disease, how can this "increased resistance" of the tissues be brought about? Is there any ground for believing that the tuberculous glandular lesions will be at all influenced by abdominal section, which has proved so efficacious in the peritoneal type of tuberculosis?

The writer has been led to a consideration of these questions by a study of the three cases of mesenteric disease detailed above. The improvement, and in one case cure, following abdominal section, where the peritoneum was not involved and the tuberculous disease confined to the mesenteric glands, has suggested the advisability of the adoption of this treatment in cases of this description.

The limits of this paper forbid the consideration of more than beginning, uncomplicated mesenteric glandular enlargements. Ablation of these glands as a curative surgical procedure will not be considered,

The peritoneum may be considered as a large lymph-sac, lying upon and directly continuous with lymphatic channels, for which the mesenteric glands act as filters. Hence, it is not unreasonable to suppose that certain marked physiologic changes in the peritoneum will, to some extent, affect these lymphatics with which it is so intimately connected, and that through these means changes will be wrought in the mesenteric glands.

It is pretty generally recognized that the cure of tuberculous peritonitis is in some manner accomplished by the mere opening of the abdominal cavity. At the time of the appearance of König's⁸¹ now classic paper, it was thought that the cure of peritoneal tuberculosis was largely dependent upon the use of iodoform and antiseptic irrigation. In a second paper, six years later, König⁸² analyses 130 recorded cases of tuberculous peritonitis, in all of which a major operation had been performed. The nature and amount of manipulation, however, did not seem to effect the result, nor did the nature of the disinfectants used. At present, the consensus of surgical opinion is against irrigation and drainage in this class of cases, better results following their omission.

A great many theories have been advanced explanatory of the cure of tuberculous peritonitis following celiotomy, none of which can be said to be entirely satisfactory. Any consideration of this question must take into account the natural tendency to cure in all forms of tuberculosis, notably in the osseous, lymphatic and peritoneal types of the disease. It is not progressively fatal under all circumstances, as is cancer. Tuberculous lesions may be considered in a state of unstable equilibrium, where a very slight change in the living cells near the seat of the tubercle may turn the scales in favor of retrograde changes in the tuberculous process.

No such physiologic changes can be produced anywhere in the body as a result of opening the peritoneal cavity. Tait³³ has reported the disappearance of myomatous and a marked improvement in malignant growths following abdominal section. Gusserow³⁴ has noted the same in malignant peritoneal growths, and Mackenrodt³⁵ has reported a cure of a presumably malignant retroperitoneal tumor by a simple celiotomy. Tait calls attention to the great thirst following celiotomy as indicative of the marked physiologic changes taking place in the peritoneum. The increased absorptive power of this serous membrane following section has been long recognized.

While these facts cannot be disputed, the *modus operandi* of the cure of tuberculous peritonitis through abdominal section is difficult of explanation, and has given rise to much speculation. It cannot be due to mere evacuation of the fluid and the formation of ad-

hesions which strangle the tubercle bacilli, as was held by White,³⁶ Cabot,³⁶ and Van der Walker,³⁶ for cases of peritoneal tuberculosis without effusion have been reported cured by celiotomy. Evacuation of the ascitic fluid, the restoration of normal abdominal tension and the rest thereby afforded the peritoneum, are, no doubt, important, although not the sole factors in the cure.

Cameron³⁹ holds that ptomaines are held in the ascitic fluid and favor the propagation of the disease. Lindner⁴⁰ attributes great importance to the power of absorption of the serous membrane which had been impaired by the lesions. Weinstein⁴¹ holds much the same view. Roersch⁴² maintains that celiotomy cures by relieving the ascites, which by compressing the vessels hinders absorption of the inflammatory products. Lauenstein⁴³ suggests that drainage, with consequent loss of moisture and the admission of light, prove hostile to bacterial growth. Mosetig-Morhof⁴⁴ believes that the cure results from the irritation of the peritoneum following the entrance of air. Morris⁴⁵ claims to have isolated a toxalbumin from the bacteria of putrefaction developed from the exposure of the ascitic fluid to the air, which destroys the tubercle bacilli very promptly.

All the above-mentioned theories depend upon the presence of ascitic fluid and fail to explain the curative effects of celiotomy upon the dry forms of peritoneal tuberculosis. Probably a truer explanation of the *modus operandi* has been arrived at by Nannotti⁴⁶ and Bacciochi from their experimental studies on the lower animals, chiefly dogs. Among the other conclusions of these observers may be mentioned:

1. That the disappearance of the peritoneal tuberculosis after celiotomy is by resorption and the surrounding of the tubercle with connective tissue.
2. The resorption of the tubercle occurs in consequence of the destruction of the tubercle exciters (phagocytosis) and the formation of new vessels. The latter is very marked in the experiments on dogs.
3. The physiopathologic action of celiotomy in healthy animals consists in an inflammatory reaction of the peritoneum accompanied by an increase in its resorbing power.

Evidence confirmatory of the correctness of these conclusions is furnished by D'Urso,⁴⁷ who reports a case of tuberculous peritonitis in which four operations were required within nine months. The healing process in the tubercle was well observed; an invasion of leucocytes destroying the epitheloid zone, vascular neoformation to the center of the tubercle and substitution of the latter by young inflammatory tissue. Stchégoleff⁴⁸ maintains that celiotomy causes an inflammatory action characterized by an infiltra-

tion of embryonic cells (phagocytosis) and an active development of endothelial cells. This new tissue organizes and the specific elements of tuberculosis perish or are absorbed.

Celiotomy then may be said to be the factor which furnishes "increased resistance" to the tissues, causing an influx of phagocytic cells to the diseased areas. Through the agency of these cells, either alone or assisted, the tubercle bacilli perish. Future investigations must determine whether this is accomplished by the phagocytes alone (Metschnikoff⁹) or whether the bactericidal power of the extracellular fluids play an important part (Buchner,⁵⁰ Nuttall⁵¹). The new tissue which is formed by the inflammatory process may remain as a fibrous nodule or may be completely absorbed by the peritoneum. The latter process is in reality a complete *restitutio ad integrum* as proved by secondary celiotomies in cases where the first operation revealed tuberculosis of the peritoneum. Such cases are reported by McCosh,⁵² Richelot,⁵³ Clarke,⁵⁴ and others. There is every reason to believe that the processes described above extend to the lymph-channels lying beneath the great serous lymph-sac, with resulting phagocytosis and new tissue formation in the tuberculous glands.

The mesenteric glands are usually found enlarged to a greater or less extent in cases of tuberculous peritonitis, yet this enlargement is not mentioned as still existing in those cases where secondary celiotomies have been performed, showing that the curative effects of the operation have probably extended to them. Therefore, under these circumstances celiotomy should be resorted to as soon as the abdominal symptoms are sufficiently urgent to make the diagnosis of tuberculous mesenteric glandular disease reasonably certain.

Summary.—1. Primary tuberculous mesenteric glandular disease is by no means uncommon.

2. While it may be, it is not, as a rule, secondary to intestinal tuberculosis.

3. The tubercle bacilli may pass to the mesenteric glands through the intestinal mucous membrane without leaving any visible lesions.

4. Tuberculous mesenteric glandular disease may be congenital, and the tubercle bacilli may remain latent in these organs during long periods of time.

5. Under favorable conditions, beginning tuberculous disease of the mesenteric glands can be diagnosed without the presence of palpable tumors.

6. These glandular enlargements may result in caseation or calcification.

7. In cases of caseation, the danger of extension of the tuberculous process to the peritoneum is considerable.

8. When taken in season tuberculosis is not neces-

sarily a fatal disease if, in any way, "increased resistance" of the tissues can be obtained.

9. Abdominal section produces powerful physiologic changes in the peritoneum.

10. It has been shown that all varieties of tuberculous peritonitis, the dry as well as the ascitic, are susceptible to cure by celiotomy. Hence, the theories which fail to explain the cure resulting in the granular variety are faulty.

11. The true explanation of the cure of tuberculous peritonitis resulting from celiotomy is to be found in the phagocytic action of the embryonic cells, together with the formation of new vessels and connective tissue.

12. This new tissue may remain as fibrous nodules or it may be entirely absorbed by the peritoneum.

13. From the position of the peritoneum, lying as it does upon a bed of lymphatics for which the mesenteric glands act as filters, there is every reason to believe that the same changes produced by celiotomy on peritoneal tuberculosis will occur in the tuberculous mesenteric glands.

14. Abdominal section should be advised in tuberculous mesenteric disease as soon as the abdominal symptoms make the diagnosis reasonably certain.

EARLY DIAGNOSIS AND MISTAKEN DIAGNOSIS IN CASES OF TUMOR OF THE BREAST.¹

By CHARLES A. POWERS, M.D.,
OF DENVER, COL.

THE frequency with which the female breast is the seat of a tumor is well known to all practitioners of medicine, but the difficulties attending accurate diagnosis are appreciated only by those who see many of these cases; and as correct diagnosis forms the key-note to successful management and favorable prognosis, I have felt that a recital of some of my own errors might be of value to others.

A study of cases in which the histologic condition has been at variance with the clinical diagnosis has been of much interest, and has served to impress on me the wide range of variation in symptoms which these mammary tumors present, and the ease with which malignant growth may be considered benign, or a benign growth be thought malignant. Of such vast importance in the management of malignant growth of the breast is early diagnosis that too much stress cannot be laid on the principle that every lump or nodule in the gland is to be explored unless there be some distinct contraindication; such contraindication will rarely be found. Women are prone to overlook these lumps or to conceal them, and all surgeons know how frequently they appear with a mammary tumor, which, perhaps, is as large as one's fist. The remedy for this, so far as a remedy may be found, lies in impressing on the laity the fact

that all lumps and growths are important, no matter how small they may be, and that competent advice thereon should be sought at the earliest possible moment. Physicians can do much in this way; they should lose no opportunity of informing their patients that all lumps and growths ought to be attended to, and that the benign tumor of to-day may be malignant in the future. Only too often does the family practitioner, when shown a lump in a woman's breast, say that it is unimportant, and that he will look at it again in a month or two. The woman's fears are allayed, she neglects to again call the physician's attention to the matter, and when she does seek advice the growth is very probably beyond possibility of cure. During the past month two such patients have come to my office. In each the family physician had advised delay until the growth had become large, and then had removed only the breast. When coming under observation each scar was the seat of inoperable recurrence.

To many of us these are trite words, but every surgeon knows how often unwise delay or incomplete operation leads to a speedy and fatal termination, and I feel that these principles cannot be repeated too frequently or impressed too strongly. Successful management of malignant disease may to-day be summed up in these words: Early recognition, early and thorough operation, and careful surveillance of the patient for many years afterward. Progress in this direction is steadily being made, and the future undoubtedly has in store for us results which now seem impossible of attainment.

For some years it has been my custom to enter in my case-book the provisional clinical diagnosis of a given tumor and to place opposite this, after operation, the result of the microscopic examination of the growth. These parallel columns not infrequently differ materially. Permit me to cite some of the errors:

CASE I.—Mrs. S., thirty-five years of age, was referred to me March 5, 1892, by Dr. Geoffrey R. Bourke. For some months she had noticed a small lump in the upper, outer quadrant of the left breast. This mass was about the size of a robin's egg, somewhat flattened, rounded, freely movable, and the skin over it normal, the nipple not being affected. There was nothing to be felt in the axilla or in the supraclavicular space. The "feel" of the tumor seemed to be that of a fibro-adenoma, and the patient and her husband were advised that the growth was probably benign, but that it possibly might be found to be malignant. Their consent was obtained to a complete operation in case it was thought advisable. On cutting into the growth it seemed to be malignant, and the breast, pectoralis major muscle, and axillary contents were excised. Microscopic examination of the growth proved it to be a medullary

¹ Read before the Denver and Arapahoe Medical Society, April 13, 1897.

carcinoma. One small malignant gland was found in the axillary fat. The patient had a secondary mass removed two years later and died of internal recurrence at the end of three years.

CASE II.—This case was similar to the foregoing, except in that the mammary lump, which was the size of an almond, seemed to be so certainly benign that it alone was removed. The microscope showed it to be carcinoma, whereupon the "complete" operation was performed. There were two or three small malignant glands in the axilla. This patient is free from recurrence, and it is now more than five years since her operation. She was thirty-two years old at that time.

CASE III.—Mrs. X., forty years of age, was referred to me during June, 1893, by Dr. T. T. Janeway of New York. For some months she had noticed the progressive growth of a lump in the right breast. Examination revealed an irregular mass the size of an apple in its inner, upper quadrant. This mass was deep seated; it seemed to be hard and partially fixed. Provisional diagnosis of carcinoma was made. At the time of operation an incision was made into the mass, and it was found to be a simple cyst. This alone was dissected out.

CASE IV.—This was another instance of the same error. The patient, a woman thirty-eight years of age, was referred to me by Dr. Jas. A. Hart of Colorado Springs during February of the present year. A week before I saw her she first noticed a mass the size of a small fist in the upper, inner quadrant of the right breast. She at once showed this to Dr. Hart, who pronounced it cancer and immediately sent her to me for operation. On careful examination I could not doubt that the growth was malignant. It was hard, nodular, and non-fluctuating; it seemed to be carcinoma. At the time of operation incision into it revealed a large, irregular cyst. This was dissected out. At one or two places the cyst wall seemed to be hard and suspicious-looking, and Dr. H. C. Crouch, who was present, examined it microscopically, but failed to find evidence of malignancy.

In each of these instances incision into the tumor at the time of operation revealed the cystic nature of the growth. The exploring needle before operation would have shown as much, but the diagnosis seemed so fairly certain that I did not make use of it. We are not to forget that cysts and abscesses sometimes are mistaken for malignant growths and an entire gland needlessly sacrificed. I myself came very near doing this in Case V., in which a mass, which I thought was probably carcinoma, proved on incision to be a hematoma (New York Cancer Hospital), and in another (Case VI. of the present series), in which I mistook tuberculosis of the breast for cancer. Fortunately, the entire breast was not sacrificed in the first of these instances, though it was deliberately removed in the second. I was not so fortunate, however, in Case VII., for in

this I removed the breast and axillary contents for a small lump, which seemed at the time of operation to be carcinoma, but which the microscope showed to be a fibro-adenoma. Some of you may remember that I reported the case to this Society some eighteen months ago, contrasting it with another in which a small lump, which seemed at the time of operation to be benign, proved to be malignant, and I was obliged to return and complete the removal of the breast, pectoralis major muscle, and axillary contents. Added cases have served to impress upon me the value of a microscopic examination of uncertain, or, indeed, of fairly certain, tumors at the time of operation. This consumes but a few moments, perhaps eight to twelve minutes, and may be of great diagnostic value. So, when a tumor, which we think to be benign, is found by the pathologist to be malignant, our course is clear, while if he fails to find evidence of malignancy we are justified, in ordinary cases, in removing the growth itself, submitting it to him for thorough examination, and being governed by his final report as to further procedure.

True, there are many breast tumors in which we need no evidence in addition to the clinical signs, indeed, the majority fall in this category, but there are many in which we require all possible aid. An excellent illustration of this, though in another part of the body, came under my observation a few weeks ago. A young man, twenty-six years of age, came to me with a small tumor of the parotid, which I thought, without doubt, was benign. I removed it and sent it to Dr. Crouch, who pronounced it myxomatous carcinoma, whereupon I was forced to return and remove the entire parotid gland and the adjacent tissues. In passing, it may be said that Dr. C. B. Porter, who wrote the excellent article in Dennis' "System of Surgery," says of these parotid tumors: "The diagnosis, and the decision to attempt removal of the tumor only or of the whole gland, should be controlled by the microscope at the time of operation, when possible."

Exceptional lumps in the breast may warrant delay and watching, but this delay is not to be made without careful thought and study. I have seen three instances of what Mr. Herbert Snow calls "Dispersible Tumors of the Breast," lumps which disappeared in a few weeks or months. One of these was in a little girl seven years of age, from whose mother I had removed a fibro-adenoma of the mamma.

Such admirable papers have been recently published by Bull, Richardson, Warren, Halsted, and others, that I refrain from speaking of the provisional differential diagnosis and management of mammary neoplasms, and content myself with endeavoring to

impress upon you the absolute importance of the earliest possible attention in such cases, as well as my own conviction, a conviction based on the operative care of some ninety patients with breast tumors, that accurate clinical diagnosis is often difficult, and, indeed, at times impossible.

CATARRHAL SORE THROAT IN GENERAL PRACTICE.¹

By J. M. G. CARTER, M.D.,
OF WAUKEGAN, ILL.;

PROFESSOR OF CLINICAL AND PREVENTIVE MEDICINE IN THE
COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

DURING the spring of 1897 the prevailing wind on the western shore of Lake Michigan, in Northern Illinois, was from the lake, much of the time from the northeast, and sometimes from the southeast. The season developed many cases of catarrhal sore throat, especially during the periods when the northeast wind was the prevailing one. So marked was this that a practitioner at the time expected a new contingent of patients affected with sore throat when he arose in the morning. On the contrary, if the wind prevailed from the west, if for only a few days, the disease rapidly declined, and no new cases occurred. At one time the northeast wind prevailed for two weeks, and during this period the affection was particularly obstinate. In one instance, in a patient susceptible to sore throat, in whom, under ordinary circumstances, similar attacks have been controlled after three or five days, the sickness was prolonged to ten days, and there was no appreciable cause for this persistence except the continued lake wind. Many such cases were encountered, so many, in fact, that the affection was marked as an unusual divergence from the typical cases of catarrhal sore throat so frequent in this region.

The doctrine that the lake winds have a very decided effect upon the presence and occurrence of catarrhal forms of sore throat seems to be a rational and scientific conclusion. The humidity and temperature, the character of the winds, their force and direction, and the presence or absence of ozone in the atmosphere exert a marked influence upon the prevalence of these diseases, either by their effect *per se*, or by creating a congenial soil or favorable culture medium for the bacteria which accompany most of these cases. I have elsewhere² given an extended discussion of this subject and need not enter into further consideration of it here.

These cases commence with a sense of stiffness or rigidity, and a dryness or uncomfortable feeling in the throat, sometimes with pain upon swallowing.

There is a general feeling of malaise, occasionally muscular aching or soreness, which not infrequently is accompanied by rigor, or chilliness, and consequent fever. Thirst, anorexia, and at times nausea, are present. The tongue is coated. Often, there is a particular spot in the throat mentioned as being especially painful, as in the invasion and progress of suppurative tonsillitis. Headache is a common symptom. Restlessness and insomnia occasionally exist. Itching in the nasopharyngeal region and in the ears is common and very annoying. Some cough is present in many cases, without expectoration at first, but later, sputum, consisting chiefly of mucus, is easily raised. Hoarseness is common and aphonia frequent. The two chief features which have distinguished these cases from similar epidemics during previous years are the persistence of the attack and the frequent presence of aphonia. If one member of a household is affected all are likely to be. Occasionally the inflammation extends downward beyond the larynx, and the symptoms and signs of bronchitis appear. The appearance of the throat upon examination is characteristic. The mucous membrane is red, the redness extending over and involving the surface of the tonsils, fauces, pharynx, base of the tongue, and larynx.

In many cases there is a point of intensity of redness, especially sensitive to touch, usually located in the fauces, or on one of the tonsils. This is where the greatest distress is experienced when swallowing, and at the same time, especially when this point is located on the tonsil, the patient in some instances complains of a cramp-like sensation. In the work already referred to I have shown that micrococci are abundant in these catarrhal sore throats, and in the cases here mentioned the chief habitat of these organisms, or at least the point of concentration, is in the area of intense redness just mentioned.

During the first few hours of this disease the mucous membrane is dry and secretion limited, but the membrane is swollen and thickened. This condition extends to and involves the larynx and vocal cords in many cases, hence the hoarseness and occasionally the aphonia. After one or two days the mucous covering is moistened by an exudate, and by an increase of mucus, and the most distressing symptoms are allayed or somewhat abated. The infiltration not only causes swelling of the mucous membrane, but it often involves the submucous tissues and almost closes the throat by the enlargement of the tonsils, the tumefaction of the fauces and the fulness of the deeper structures of the pharynx and larynx. The involvement of the tonsils can be considered only as a phase of the disease, since it was so common; but only one patient in about seventy de-

¹ Read at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

² "Catarrhal Diseases of the Respiratory Passages," by J. M. G. Carter, M.D.

veloped suppurative tonsillitis. There were cases in which the inflammation involved the deeper structures but in which resolution occurred before suppuration supervened. No cases of diphtheria occurred during the period here included. The papillæ on the base of the tongue were frequently enlarged and red, dry at first, but later moist.

The pathology of these cases is simple, being that of an ordinary catarrhal inflammation. If the cause is merely climatic, the changes of humidity and temperature, or ozone, or the wind act directly upon the mucous membrane and produce an irritation; if the cause is bacterial, the point of inoculation is the throat, and possibly the area of greatest intensity of redness. In either case, the first effect seems to be an instantaneous, or at any rate very brief, contraction of the minute vessels, followed immediately by dilatation of the capillaries, and increased rapidity of circulation. When the terminal vessels become engorged, the blood flow is retarded, and, later, stasis, or a condition approaching this is reached, and diapedesis occurs. This is the stage of exudation upon the surface or infiltration in the deeper structures. These cases generally stop at this stage of the pathologic process and resolution begins, very few of them passing on to suppuration, as in quinsy. The duration, under ordinary circumstances, is from three to five days, but, as already intimated, a large number have been prolonged this season to ten days.

The cause and pathologic condition suggests a rational course of treatment. The presence of bacteria in all cases, and of pathogenic bacteria in many, makes it advisable to employ germicides for cleansing purposes. The congestion requires soothing and some times astringent applications. When the first stage is passed and that of exudation begins, the same kind of local treatment produces good results. The fever and muscular soreness require internal treatment.

In the local treatment I have used many different preparations in the search for some one which would give quick and satisfactory results. The quickest cure in my experience has resulted from the use of a mixture consisting of equal parts of tincture of iodine, glycerin, and carbolic acid, of Löffler's toluol solution, or of hydrozone in the order named. These may be applied by means of a cotton pledget attached to a stick. The solution should be kept in contact with the diseased part during ten or fifteen seconds, after which the patient may use a gargle of sterilized water. The applications ought to be made twice a day, and a gargle of permanganate of potash used every half hour or hour during the intervals between treatments.

If a milder and more soothing application is required, eucalyptol and bismuth compound may be used. This preparation, as well as hydrozone, may be conveniently used with an atomizer. In many instances, especially in children, the first two preparations given above will not be used, and some other will be necessary. In these cases nothing is better than hydrozone, and as this may be used as a spray in from twenty to twenty-five-per-cent. solution, it is also a convenient remedy. A peculiar tickling which induces cough will instantly be relieved by it. Local treatment for the larynx should consist chiefly in inhalations of the atomized vapor of hydrozone, menthol, eucalyptol, and bismuth compound with the essential oils. The air of the patient's room should be kept at a relative humidity of about seventy-four per cent.

Internally I have used with marked success a tablet consisting of two grains each of acetanilid and salicylate of soda, and half a grain each of quinine sulphate and caffein citrate.

When these cases are neglected, and when the initial treatment has been improperly carried out, they frequently pass into a chronic state. The treatment may then require considerable modification. Hydrozone may still prove of great benefit, and frequently surpasses all other means of cure. It may be used by atomization in twenty-per-cent. solution, or as a gargle. Hot wine, whisky, and alcohol gargles twice a day stimulate the local circulation and cleanse the mucous membrane of tenacious secretions and exudations. Menthol, by inhalation or in weak solution as a gargle, acts well in some cases, relieving hoarseness and soreness. It is an antiseptic and anodyne and contracts the capillaries, thus diminishing secretion. The essential oils may be used by nebulization, with very marked relief in many instances.

The most important treatment in chronic catarrhal diseases of the throat, like that in chronic bronchitis, is a change of climate. A dry, warm, and equable climate is required in most instances, but frequently a moist climate is better. When this change cannot be secured, certain protective and prophylactic measures are advisable. Removal of mufflers from around the neck and the substitution of a silk handkerchief in front of the throat when out of doors in cold weather is to be recommended. Daily morning ablutions of the neck, throat, and chest with cold water, and gargling of the throat and washing of the nose with the same are of great service. Patients who are obliged to be out every day will find it advantageous to use a gargle twice daily consisting of alcohol and glycerin, each fifteen per cent., and water seventy per cent. This has the effect of

strengthening the resisting power of the mucous membrane. General tonic measures are often necessary, as in the treatment of bronchitis.

CLINICAL MEMORANDUM.

A CASE OF GUNSHOT WOUND OF THE BRAIN, CAUSING PARALYSIS OF THE ARM; RECOVERY.

By J. B. FATTIC, M.D.,
OF ANDERSON, IND.

OTTO L., nine years old, on February 22, 1897, was shot in the forehead with a 32-caliber revolver. I found the patient unconscious, there being moderate, irregular convulsive movements, except in the left arm, which was paralyzed. The pulse was very rapid and scarcely perceptible, the skin pale and cold, and respirations irregular and shallow. There was a small, circular wound about half an inch above the right superciliary ridge and one inch to the right of the median line of the forehead, which extended through both tables of the frontal bone and into the brain.

A sterile olive-tipped probe was carried upward, backward, and slightly outward along the track of the bullet

FIG. 1.

Skiagram of a 32-caliber bullet lodged in the brain. Trans-frontal exposure.

about three and one-half inches, but the missile, not being detected at that depth, or in the vicinity of the entrance-wound, it was deemed best to desist from further attempts to locate it. A few small bone splinters, a small amount of brain substance, powder-grains, and blood-clots were removed, the slight hemorrhage was checked, and the wound irrigated with sublimate solution, sutured, and covered with sterile iodoform collodion gauze.

After free stimulation, reaction from shock soon occurred and the patient became semiconscious, remaining so for five days, after which time he was rational. In spite of attention given to the powder-burns, considerable purulent conjunctivitis occurred, but the wound fortunately escaped infection and readily healed, although it was in close proximity to the pus.

The paralysis of the left arm continued complete until the seventh day after injury, when rapid improvement began and resulted in recovery in a few days, except a slight degree of muscular weakness. The boy returned to school a few weeks later and now, seventeen months afterward, is apparently as well as ever, no unfavorable symptoms having appeared.

FIG. 2.

Skiagram of a 32-caliber bullet lodged in the brain. Fronto-occipital exposure. A wire was so placed as to show the median line of the forehead.

The accompanying skiagrams were recently secured for the writer by Mr. B. P. Remy, of this city. The transfrontal exposure was but eight minutes and the fronto-occipital exposure but twenty minutes, a matter of decided advantage when a restless patient is the subject. In the fronto-occipital skiagram (Fig. 2) a wire was placed so as to show the median line of the forehead.

From the history of the case it is evident that the motor area of the right side of the brain, controlling movements in the left arm, was injured, and the early relief from the paralysis and the present location of the bullet, as shown by the skiagrams, warranted the belief that the missile must have retraced its passage along the brain-wound, assisted by the force of gravity.

MEDICAL PROGRESS.

Purulent Pericarditis Cured by an Operation.—GARBER reports, in *The Jour. Amer. Med. Assn.*, June 26, 1897, a case of purulent pericarditis in a girl aged twenty-one, produced by puncture with a steel crochet-needle in the fifth left interspace, which was rapidly and completely cured by incision and drainage. The hook of the needle carried a thread into the pericardium, and it remained there

twenty-four hours before being removed, causing septic pericarditis, with fever and restlessness, but neither chills nor pain. Operation was finally consented to, and was performed fourteen days after the accident. Through the fifth space the pericardium was opened, and with the help of the finger and irrigation, a quantity of pus and masses of purulent blood-clots were removed. The cavity was drained with a wick of iodoform gauze. Twenty-four days after the operation the patient was discharged cured.

Strangulated Hernia Twenty-seven Years After Ovariectomy.—In the *Amer. Jour. of Obstetrics*, June, 1897, an interesting sequel of events is described by STOKES. During 1869 an ovariectomy was performed by Atlee upon a woman aged forty-eight. Adhesions were very troublesome, and the operation lasted four hours. The patient was not expected to live, but she recovered after a long period of suppuration and went actively about her duties, with a ventral hernia, until last February, when, at the age of seventy-five, the hernia became strangulated and death ensued in chloroform narcosis during preparation for operation. The strangulation was brought about by pressure of the ring upon a loop of ileum contained in the sac, at a point where long-continued pressure had reduced its caliber to almost nothing.

Examination of Typhoid Stools.—RICHARDSON (*The Jour. Amer. Med. Assn.*, July 3, 1897) finds that the examination of the stools of typhoid patients has a value in diagnosis only second to that of the serum test. In 13 cases of active typhoid he was able, by using a new agar medium, to isolate typhoid bacilli in 10 instances, while of 29 non-typhoid individuals whose stools were examined not one showed the presence of bacilli. All of the cases in which bacilli were found gave a positive serum reaction at least two days before the bacilli were found in the stools, so that the test is decidedly inferior to that with serum, though it has a value as a confirmatory test, especially in doubtful cases. It was also found that although the organisms rapidly diminish with beginning convalescence, they do not entirely disappear for several weeks, a point of importance in connection with disinfection.

The agar preparation used, and which was found to give great satisfaction, was that recommended by Cappaldi, which contains enough chlorid of potash to prevent the growth of many forms of bacteria. The appearance of the coli colonies and those of typhoid, are so different that it is much easier to tell them apart than has been the case on the culture media heretofore employed.

THERAPEUTIC NOTES.

Treatment of Inoperable Cancer of the Uterus.—ROBINSON (*North Carolina Med. Jour.*, July 5, 1897) treated two patients suffering from advanced cancer of the uterus in the following manner, with good results: Through an abdominal incision the uterine and broad ligaments were divided to relieve the pain which their tension caused. The ovarian and uterine arteries were ligated. By means

of a long needle alcohol was injected per vaginam into the indurated tissues about the uterus, every third or fourth day, at first 30 minims, and then an increased amount up to 100 minims. The injections were rather painful, and were followed by a flushed feeling. After two-months' treatment there was a cessation of all discharge and odor, in one case, while the pain was abolished, irritability of the bladder was much reduced, and the general condition of the patient was greatly improved. There was a marked diminution of the indurated area. In the other case, a septic condition existed at the beginning of treatment, and could not be relieved until two doses of antistreptococcic serum were administered. The local results in this case were similar to those in the less advanced one, but the time is yet too short to say whether the good effects of the injections can be maintained.

In *Der Frauenarzt*, May, 1897, CZEMPIN describes a method of treatment of inoperable cancer of the uterus by which he has obtained, "in the least favorable case, an absence for a year of all symptoms of cancer." In other cases the results were more lasting, and one woman has been kept in good health for more than four years, the treatment being twice carried out during that time. After a thorough curetting of the affected portions, the whole diseased surface is thoroughly gone over with a red hot iron, so that a hard crust is everywhere formed. If there is any tendency to hemorrhage, the iron is heated hotter, and held close to the bleeding point without touching it, in this way cooking the tissues and at once stopping the bleeding. Two or three yards of a two-inch strip of iodoform gauze is saturated with a solution of the sesquichlorid of iron, squeezed dry and packed into the uterine cavity. This is removed after three days, and daily irrigations of lysol are made. After a week or more the cauterized slough comes away, and a mass of zinc paste, corresponding in size to the cavity of the uterus, is put on a strip of gauze a yard long and placed in the cavity. The formula is:

R Chlorate of zinc . . .	3 vi, gr. xv
Starch . . .	3 liiss
Gum tragacanth . . .	q. s.

The gauze and paste are to be removed *in toto* after five hours at the latest. The pain is often severe, requiring the administration of morphin. If carefully applied there is little danger from hemorrhage; but at the time that the slough is loosening the tags of slough still containing much of the zinc may come in contact with the fresh granulating surface, and so cause bleeding. On this account, it is well to supervise the sloughing, and to cut away the loosened portions from day to day. The scar formed is a firm one, and pain and discharge are banished for months, or even for years, as said above. Czempin has tried alcohol injections, but with only temporary benefit.

Pirogof and Anesthesia.—The recent erection of a statue to the great Russian anatomist and surgeon Pirogof recalls the fact that the first operation performed under ether in Russia was done by him.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, AUGUST 28, 1897.

THE BRITISH MEDICAL ASSOCIATION.

THE sixty-fifth annual meeting of the British Medical Association will be held in Montreal, beginning August 31st and continuing four days. Great fears have been entertained in some quarters that the American members of the profession would not be especially welcome at this meeting. It is natural that American physicians should desire more intimate acquaintance with their brethren of the British Isles, and this meeting seemed to present a convenient opportunity for seeing their faces, hearing their voices, and pressing their hands in cordial fellowship. The present indications are, however, that the American physicians will be quite as much in evidence as the members of the Association, and there is some apprehension lest the many invited guests from the States will be largely entertained by the familiar voices and ideas of their own countrymen. The complete official program, however, may change present indications somewhat.

The preliminary announcement, which appears in another column, gives assurance of a most interesting meeting and guarantees an expression of opinion by representative men in each department of medicine.

This is the first time in the history of the Association that it has held a meeting in any of the colonies. Canada naturally feels greatly complimented, and the local profession of our honored neighbor is leaving no stone unturned in a united effort to render this a most interesting, instructive, and delightful occasion. The readers of THE MEDICAL NEWS will await with interest the condensed report of this meeting which will appear in the succeeding numbers.

IMPERFECTIONS OF KOCH'S NEW TUBERCULIN.

No principle of medical science is accorded more general acceptance to-day than that of serotherapy. Every experiment in this line of work but adds confirmation to the general opinion regarding it. At the same time there has grown up in the minds not only of the general practitioner but also of the laboratory expert a true scientific skepticism, which insists that every new discovery shall be subjected to the crucible of personal investigation. Fortunately there are many well-equipped and widely scattered laboratories where these tests can be applied free from personal bias or prejudice.

While these conditions prevail we are free from the danger of premature announcements of important discoveries; indeed, the prompt dissemination of these various laboratory experiments enables the valuable and enduring parts of a discovery to be carefully sifted from the non-essential, and sources of error to be eliminated. In another column will be found an article of Drs. Trudeau and Baldwin, of Saranac Lake, N. Y., giving the results of their careful investigation of Koch's new tuberculin. They point out that the first requirement of an injection fluid is that it be entirely free from danger, and, without affirming or denying the possibilities that may arise from the use of "T. R." tuberculin containing tubercle bacilli, they have discovered that as a matter of fact the new preparation is not absolutely free from these organisms.

This is a most important discovery and suggests the imperative necessity of improved methods in the process of manufacture. An immunizing fluid, or a test fluid designed to indicate the presence or absence of disease in a suspected case, above all things should be free from the suspicion of conveying disease, either the one against which immunity is

sought, or any other. And the danger of primarily inoculating with a virulent germ a patient in whom there has been a mistaken diagnosis "must give us pause." *Non nocere!* is the primal law of therapeutics, and in its execution the strictest conservatism must prevail.

This investigation into the quality of tuberculin and the inaccuracy of its preparation by the manufacturers is along the same line of enquiry that was conducted last year by THE MEDICAL NEWS into the quality of diphtheria antitoxic serum. It is with no little pride therefore that THE MEDICAL NEWS is now the first to present through Drs. Trudeau and Baldwin this discovery of a vital error in the manufacture of the improved tuberculin and at the same time present a method of correcting it.

Koch's claim of having solved the problem of producing artificial immunity against tuberculosis by a liquid containing soluble substances obtained from the dried and crushed bodies of virulent tubercle bacilli is such a logical departure in this line of research work, and the subject is of such overwhelming interest that it is to be hoped careful experiments on animals by others may soon confirm the correctness of his views. Meanwhile it is greatly to be regretted if on account of the many technical difficulties to be overcome in the manufacture of the new "T.R." tuberculin a general test, in the human subject, of the therapeutic value of the remedy in the treatment of tuberculosis may be somewhat delayed. There can be but little doubt, however, that these difficulties will eventually be overcome.

ECHOES AND NEWS.

Typhus Fever in Liverpool During 1896.—During the year 1896 there were 305 cases of typhus fever, with thirty-six deaths, in Liverpool, Eng.

Appropriation for the Philadelphia Polyclinic Hospital.—An appropriation of \$25,000 has been granted by the State of Pennsylvania for the maintenance of the Philadelphia Polyclinic Hospital.

Dr. Sanarelli Honored.—The legislature of Uruguay has conferred honorary citizenship and the sum of \$10,000 upon Dr. Sanarelli in recognition of his discovery of the bacillus of yellow fever.

Kneipp Cure at Mamaroneck, N. Y.—A large tract of land has been purchased at Mamaroneck, N. Y., upon which a Kneipp-cure institute will be established. The main building will be about 400 feet long.

A Sanatorium in a Desert.—A sanatorium for rheumatic and lung patients has been established at Heluan, Egypt, sixteen miles from Cairo with which it is connected by railroad. The air is said to be of unrivaled purity and dryness.

The Babies of Paris.—It is said that a resolution has been submitted to the Municipal Council of Paris requiring families to furnish every two months a medical certificate stating that infants under one year have been cared for in accordance with hygienic rules.

X-Rays in a Murder Case.—A man recently died in Elmira, N. Y., presumably as a result of a bullet-wound of the head. The attorney of the man who shot him now contends that death was due to the effects of the X-ray which was used to locate the bullet.

The Oldest Doctor.—In the issue of THE MEDICAL NEWS of the 14th inst. reference was made to Dr. Stephen Adams of West Newfield, Mass., as the oldest physician in the United States. A correspondent writes us that Dr. Adams lives at West Newfield, Maine.

Swiss Sanatorium Burned.—It is reported from Baden, a canton of Aargau, on the Limmat, the locality of the famous hot mineral springs, that a great fire almost destroyed the Neue Kuranstalt Baden, or Grand Hotel. There was a panic among the guests, and two lives were lost.

Professor Lincoln Injured.—Professor Lincoln of the University of the State of Wisconsin was badly injured on the 13th inst. by an explosion which occurred while he was conducting some experiments in the chemical laboratory. He was unconscious for some hours after the accident, but is now recovering.

Pill-takers of the World.—It is estimated from stamp duties paid by patent-medicine makers in Great Britain that 4,000,000 pills are consumed weekly in that kingdom. France takes only half that number, and Russia only 1,000,000 a week. The Australians are said to be the greatest pill-takers in the world.

Apoplexy in the Surf.—J. Sergeant Price, a well-known lawyer of Philadelphia and president of the Law Alumni Association of the University of Pennsylvania, died at Cape May, N. J., on the 16th inst. from apoplexy and exhaustion caused by struggling in the surf while bathing. Mr. Price was sixty-five years of age.

Negro Women as Nurses.—An association has been incorporated in Columbia, S. C., for the maintenance of a hospital and training school for nurses for the purpose of educating a limited number of colored women as skilled nurses. It is said that Southern hospitals where negro patients are admitted will be glad to have negro nurses.

Expelled from the British Medical Association.—At its recent meeting in London, the British Medical Association expelled two of its members for having accepted offices under the Government of South Australia in the General Hospital of Adelaide, which was vacated by the whole staff as a protest against the conduct of the government.

Medicine for the Mind.—In a book which has just been published in Paris, the author discusses the treatment of laziness, grief, anger, etc., which he considers mental affections. He devotes an entire chapter to love, which he declares to be a human malady whose symptoms resemble wonderfully those of alcoholism and morphinomania.

Medical Responsibility.—A French surgeon was recently condemned to two-months' imprisonment and a fine of 500 francs because of the death of a patient upon whom he had done a laparotomy for the removal of a fibroid tumor, and in whom a pair of forgotten forceps was found *post-mortem*. He entered an appeal, with the result that his imprisonment was increased to three months.

Pennsylvania and Maryland Union Medical Association.—The twentieth annual reunion of this association was held at Highland Park, York, Pa., on Thursday, August 26, 1897. The program consisted of a dinner, followed by a "flow of soul," under the direction of Dr. Joseph Price of Philadelphia, President of the Association, and a business meeting for the election of officers.

The Plague and the Black Death.—It is reported that Dr. Yersin, the eminent Swiss scientist and pupil of Pasteur, declares his conviction that the plague which has been raging in Southern China since 1894 and in British India since 1896, is identical with the black death of the middle ages. He also expresses the opinion that it will, in all probability, reach Europe within a year or two.

The Feather Duster a Breeder of Disease.—According to a well-known scientist, the dusting of rooms is perilous to the members of the household in that it disseminates disease germs, which have a decided affinity for dust particles and adhere closely to them. Household furniture should be wiped with a soft cloth, the dust being carefully retained in its folds. The cloth (or cloths) should be thoroughly boiled daily.

The Prince of Wales and the College of Physicians.—His Royal Highness, the Prince of Wales, on being admitted to the Honorary Fellowship of the Royal College of Physicians of London, was presented with a diploma on vellum, illuminated with the college arms, contained in a case of red morocco, and with a gold-headed cane having a vinaigrette in the head to ward off infection, after the fashion of those formerly carried by physicians.

Death Caused by Cancer-Cure.—A young woman died recently in England from arsenical poisoning caused by a plaster, the active ingredient of which was arsenic, which was applied in order to cure cancer. The epidermis was first removed by a blister, the plaster applied, and the patient told to wear it for fourteen days. The quack who applied the plaster was indicted for manslaughter, but was acquitted because he was able to prove that the woman wore the plaster twenty-one days.

Marine Hospital Service.—Dr. Joseph J. Kinyoun, Passed Assistant Surgeon, U. S. Marine Hospital Service, has been appointed by the Secretary of the Treasury to represent this government at the international exposition on

hygiene and sanitary service on shipboard, to be held in Brussels in September. He has also been instructed to visit the several bacteriologic laboratories on the Continent for the purpose of obtaining information as to recent advances in the investigation of contagious diseases.

An Unrequited Benefactor.—It is said that Dr. H. R. Silvester, whose discovery of a method of restoring persons after apparent cessation of respiration has saved many hundreds of lives, has received no adequate personal reward or distinction for the great benefit he rendered humanity. The only recognition which Dr. Silvester has received is the presentation of the Fothergill medallion awarded him by the Royal Humane Society, which, although a high honor, is not distinction enough for the important services rendered.

Healthfulness of Laughter.—An English scientist, Dr. H. Campbell, has written an essay dealing with the physiologic effect of laughter. When we laugh, he says, we increase the play of the tension of the lungs, and that one result of this increased tension is to arrest the blood-flow in the lungs and thus induce the taking of deep inspirations. These latter are healthful processes, for many parts of the lung are not called into active use during ordinary breathing. Hence, laughter is an exercise and a good one.

The Atlanta Medical and Surgical Journal's Opinion of Osteopathy.—"Osteopathy is the veriest nonsense and quackery that has disgraced an age already rich in many species of medical humbuggery. It is fit associate for Christian science and orificial surgery. The so-called philosophy upon which these three miserable fakes base their existence is words, words, words, full of sound and fury, signifying nothing. One wonders where the boasted enlightenment of the Victorian era can be when osteopaths, Christian scientists, divine-healers, faith-curists, and other voodooes can find willing victims."

Health Reports.—According to the report of the Supervising Surgeon-General of the United States Marine Hospital Service for the week ending August 14th, there were 16 deaths from smallpox at Barcelona, Spain, and 12 at Pernambuco, Brazil; 10 cases with one death at Nagasaki, Japan; 9 cases with 2 deaths at St. Petersburg, Russia. There were 96 deaths from cholera at Calcutta, India, and 15 at Bombay. Yellow fever is still raging in Cuba, there being 16 deaths from this disease at Cienfuegos, 17 at Santiago, 6 at Matanzas; 13 cases with 5 deaths are also reported at Panama, U. S. of Colombia.

Insanity in State Prisons.—The State Prison Commission has made a demand on all the penitentiaries of the State of New York for a report giving the number of convicts therein confined; the number employed; the number idle; their hours of employment; the several kinds of employment; the condition of the prisoners compared with that of a year ago, and the number of cases of insanity which have developed since January 1st, 1897. This action is taken in consequence of the large number of cases of insanity which have developed on account of idleness, in the Kings County penitentiary.

Hot Weather and Crime.—Officers of the Weather Bureau at Washington are conducting an investigation in regard to the connection between atmospheric conditions and crime. Dr. Willis L. Moore, chief of the bureau, who is a physician as well as a meteorologist, says that during the months of January, February, and March, 1200 suicides were reported in the United States, while in July, August, and September, there were 1600. During the cold period there were 1700 murders and 2500 during the three hot months. There were 50 persons hanged or lynched during the three cold months, and 113 hanged or lynched in the three hot months.

A Case of Cæsarean Section.—The Cæsarean operation was performed on August 19th, at the New York Maternity Hospital, Blackwell's Island, by Dr. J. Clifton Edgar, upon a colored woman, the subject of a generally contracted rachitic pelvis, with spinal curvature. Height of patient 4 feet 8½ inches. The indication for the operation was looked upon as an *absolute* one by the attending surgeons who examined the case, as the true conjugate of the pelvis, measured manually and instrumentally with the Farabœuf pelvimeter, the patient being under chloroform, was found to be 2¾ inches. The patient was in her thirty-eighth week of pregnancy and not in labor at the time of operation. Rapid bimanual dilatation of the os was performed as a preliminary and precautionary measure to secure thorough subsequent drainage. The operation occupied forty minutes and a living female child, weighing five pounds, 17½ inches long, and with a biparietal diameter of 3½ inches, was readily extracted. Nine days after operation mother and child are in excellent condition, the mother nursing her child. Highest temperature of patient during this period 100.4° F.

Delegates to the Congress at Moscow.—The Congress convened at Moscow on the 17th inst., and was in session four days. The scientific exercises have therefore been completed and the junketing expeditions are now at their height. Reports of the experiences of "distinguished American physicians" *en route* for Moscow have come from various parts of Europe. Those whose breasts are inspired with a warlike spirit have visited the gory battlefields of Greece, where retreat was so rapid that no saber or bayonet thrusts were received, and the principal wounds to be inspected were made by spent balls and fragments of remotely bursting shells as described in Dr. George R. Fowler's letter from Athens, which appeared in last week's issue. Those of a more bibulous tendency are reported as consuming fabulous quantities of *pure water* at the various spas. One party, among them Drs. N. Senn, D. R. Brower, and L. Waite of Chicago; F. M. Lloyd, New York; Professor G. R. Fowler, Brooklyn; Drs. W. H. Forwood, U. S. A., Washington, D. C., and W. F. Southard of San Francisco, have recently, it is reported, visited the Hunyadi Janos Springs (Saxlehner) at Budapest for the purpose of inspecting the plant and the methods employed in drawing and bottling this well-known medicinal water. While the worshipers of royalty have been kissing the hand of the Czar in the Peterhof Palace.

The Hospital Reform Association.—The first annual meeting of this association was held in London on the 26th ult., and the question of how to remedy hospital abuse was discussed. It was suggested that the British Medical Association was the proper body to take up the question, as it had both the money and ability to do so. It was decided, however, that the British Medical Association could not do anything in the matter unless its action could be sustained by a great majority, and that in any event nothing could be done this year owing to the matter having been referred to the Branches. Another speaker said that a solution of the difficulties of hospital abuse rested on an effectual cooperation between the hospitals, the general practitioners, and charity organizations. The formation of a Central Hospital Board was strongly advocated. A third speaker urged the abolition of the letter system, and the establishment of a system of hospital consultations in properly selected cases. Only cases selected by a practitioner should be admissible for treatment in the casualty department. The consensus of opinion was to this effect, and all were agreed that previous efforts to remedy the evil had failed because of lack of cooperation of the general practitioner. The system of giving death certificates in the out-patient departments of hospitals was also condemned.—*Brit. Med. Journ.*, July 31st.

OBITUARY.

RESOLUTIONS UPON THE DEATH OF DR. LOVE.

DRAFT OF A MINUTE ADOPTED AT THE MEETING OF THE VISITING STAFF OF THE MOUNTAIN SIDE HOSPITAL, AUGUST 16, 1897, IN REFERENCE TO THE DEATH OF DR. JOHN J. H. LOVE, MONTCLAIR, N. J.

No words can express the loss which the Mountain Side Hospital has sustained in the death of Dr. Love, or is it possible to so construe language as to give the measure of our personal loss in the death of our beloved leader.

Filled with the courage and self-sacrifice which are born of high purpose and unselfish broad-mindedness, and always willing to prefer the well-being of others to his own, he gave freely of his time and substance to the hospital.

Its good name was as dear to him as his personal honor, and from his clear and comprehensive mind came most of the suggestions by the adoption of which the enterprise has been successfully carried on. Without Dr. Love it would have failed; with him it has achieved an enviable measure of success and usefulness.

We can no longer enjoy his friendship, his guidance, his counsel, or his sympathy, but we have the brilliant example of his noble life, and of his devotion to the best interests of this hospital.

[Signed]

RICHARD C. NEWTON,
E. M. WARD,
H. B. WHITEHORNE,
Committee.

ANNOUNCEMENT.

PRELIMINARY PROGRAM OF THE BRITISH MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, to be Held at Montreal, August 31st to September 4th.

THE adjourned meeting of the British Medical Association will be held at Montreal on Tuesday, Wednesday, Thursday, and Friday, August 31st, September 1st, 2d, and 3d, 1897. President, HENRY BARNES, M.D., F.R.S.E., Senior Physician to the Cumberland Infirmary, Carlisle; president-elect, T. G. RODDICK, M.D., Professor of Surgery in McGill University, Montreal. An Address in Medicine will be delivered by W. Osler, M.D., F.R.C.P., Professor of Medicine in the Johns Hopkins University, Baltimore. An Address in Surgery by William Mitchell Banks, F.R.C.S., Surgeon to the Liverpool Royal Infirmary. An Address in Public Medicine by Herman M. Biggs, M.D., Director of the Bacteriologic Laboratory of the Health Department, New York City.

The scientific business of the meeting will be conducted in eleven sections, as follows:

MEDICINE.

President, STEPHEN MACKENZIE, M.D., London.

The following discussions will take place:

1. "The Dietetic Treatment of Diabetes," to be opened by Dr. Robert Saundby, Birmingham.

2. "Arthritis Deformans (Rheumatoid Arthritis); More Especially Its Relation to Rheumatism, Nervous Disease, and Tuberculosis," to be opened by Dr. James Stewart, Montreal.

3. "Cholelithiasis; Its Causation, Symptomatology, Diagnosis, and Treatment," to be opened by Dr. William Hunter, London, and Dr. Graham, Toronto.

The following, among others, are expected to take part in the discussions in this Section: Drs. Reginald Fitz, Boston; Jacobi, New York; Musser, Philadelphia; Pepper, Philadelphia; F. C. Shattuck, Boston; E. L. Trudeau, Saranac Lake, N. Y.; Jas. Tyson, Philadelphia; W. Wyman, Marine Hospital Service, Washington; R. L. Bowles, London; Mr. Wm. Armstrong, Buxton; Dr. Sidney Coupland, London; Professor Osler, Baltimore; Drs. S. Moncton Copeman, London; H. Handford, Nottingham; J. A. Myrtle, Harrogate; Graham, Toronto; R. Shingleton Smith, Bristol.

PAPERS.

[The list of papers is too long to be inserted here.]

SURGERY.

President, CHRISTOPHER HEATH, F.R.C.S., London. The President will give a short introductory address.

A discussion will take place upon "The Surgical Treatment of Appendicitis," which will be opened by Dr. G. E. Armstrong, Montreal. Dr. J. Ward Cousins, Southsea; Professor C. B. Ball, Dublin; Mr. Jordan Lloyd, Birmingham, will take part in the discussion.

A discussion will also take place upon the "Treatment of Cancer of the Rectum by Kraske's Operation," to be opened by Dr. James Bell.

Among those who will take part in the discussions in this Section are: Drs. W. W. Keen, Philadelphia; Collins Warren, Boston; John Ashhurst, Philadelphia; Cheever, Boston; Dennis, New York; Murphy, Chicago; McGraw, Detroit; J. C. White, Boston; Wm. T. Bull, New York; Professor C. B. Bull, Dublin; Mr. Jordan Lloyd, Birmingham.

[The list of papers omitted.]

PUBLIC MEDICINE.

President, E. P. LACHAPPELLE, M.D., Montreal.

The President will give an address on "Sanitation in Canada; Its Progress up to Date.

Dr. J. R. Kaye, M. O. H. to the West Riding of the County of Yorkshire, will read a paper on "The Relationship of the Health Officer to the Registration and Certification of Deaths."

Drs. F. Montizambert, Superintendent of the Canadian Quarantine Service, Grouse Isle, Quebec, and W. Wyman, Superintendent of the Quarantine and Marine Hospital Service, Washington, will open a discussion on the "Utility of Quarantines as Now Conducted (Inspection, Disinfection, and Isolation Stations)."

Drs. P. H. Bryce, Secretary of the Provincial Board of Health, Ontario; C. O. Probst, Secretary State Board of Health, Ohio; and H. Handford, M. O. H. to the County of Nottingham, will open a discussion on "How Far Should Mandatory Measures Go in Dealing with (a) Measles, (b) Whooping-cough, (c) Tuberculosis, (d) Leprosy?"

Drs. R. F. Ruttan, Chemist to the Board of Health of the Province of Quebec; G. W. Fuller, Louisville, Ky., and J. J. Mackenzie, Bacteriologist Provincial Board of Health of Ontario, will open a discussion on "The Respective Value of Chemic and Bacteriologic Methods of Water Analysis."

[The list of papers omitted.]

OBSTETRICS AND GYNECOLOGY.

President, WILLIAM JAPP SINCLAIR, M.D., Manchester.

The following discussions will be held in this Section on the days indicated:

September 1st.—"The Causation and Treatment of Hyperemesis Gravidarum."

September 2d.—"The Vaginal *versus* the Abdominal Route in Dealing with Inflammatory Conditions and Tumors in the Pelvis." To be opened by Mr. Lawson Tait.

September 3d.—"The Palliative and Radical Treatment of Uterine Flexions and Displacements." To be opened by Dr. Barton Cooke Hirst, Philadelphia.

[The list of papers omitted.]

PHARMACOLOGY AND THERAPEUTICS.

President, D. J. LEECH, M.D., Montreal.

The President will deliver a short introductory address.

Discussions on the treatment of insomnia, the treatment of syphilis, and diuretics will be held on September 1st, 2d, and 3d, respectively.

1. "The Treatment of Insomnia" will be opened by

Dr. C. K. Clarke, Physician to the Rockwood Hospital, Kingston, on general treatment; by Dr. R. W. Wilcox, Professor of Medicine and Therapeutics in the New York Post-Graduate School, on the value of individual drugs, with special reference to the newer hypnotics; by Dr. McPhedran, on the ill effects of and contraindications to the use of drugs; and by Dr. R. Ferguson, Lecturer on Therapeutics in the Western University, on the mode of action of hypnotics.

2. "The Treatment of Syphilis" will be opened by Dr. Whitla, Belfast. The introducer will deal with questions under the following heads: (a) How mercury and iodids are supposed to act in syphilis; (b) when should mercurial treatment be started, especially should it be given in the primary stages? (c) the various methods for its routine administration, dosage, etc., and the length of time necessary for mercurial treatment; (d) the treatment of tertiary and congenital syphilis.

(Hypodermic and intravenous medication will be dealt with by a dermatologist.)

The question of "Diuretics" will be opened from the clinical side by Dr. Barr, Liverpool, and from the experimental by Mr. Marshall, Cambridge.

[The list of papers omitted.]

PATHOLOGY AND BACTERIOLOGY.

President, WATSON CHEYNE, F.R.C.S., F.R.S., London.

The following will be the subjects for discussion:

1. "Serum Diagnosis and the Agglutinating Action of Serums," to be introduced by Professor Wyatt Johnston, Montreal.

2. "Immunization."

3. "The Bubonic Plague."

Among those who will take part in the discussions will be Professors Welch, Johns Hopkins; Crookshank, London; W. Hunter, London; Drs. A. S. Grünbaum, Liverpool; A. C. Abbott, Philadelphia; T. M. Cheesman, New York; R. Fitz, Boston; E. Hodenpyl, New York; Trudeau, Saranac, and F. F. Westbrook, Minneapolis.

[The list of papers omitted.]

PSYCHOLOGY.

President, R. M. BUCKE, M.D., London, Ontario.

The officers of this Section, believing that many of the papers already offered will be provocative of considerable debate, have determined to announce no special subjects for discussion.

PAPERS.

Bruce-Smith, Dr. R. W., Physician to Asylum for Insane, Hamilton, Ontario. Title of paper not received.

Brush, Dr. E. N. Title of paper not received.

Bucke, R. M., M.D., London (Ontario) Asylum. "On Mental Evolution."

Clark, W., M.D., Toronto Asylum. "The Reflexes in Psychiatry."

Crothers, Dr. J. D., Hartford, Conn. "Some New Phases of Inebriety in Clinical Studies."

Gooding, Dr. W. W., Washington. Title of paper not received.

Hobbs, —, M.D., London (Ontario) Asylum. "Surgical Gynecology in Insanity."

Rogers, Dr., Asylum for Feeble-Minded, Faribault, Minn. "Cases of Mongolian Idiocy."

Rohe, G. H., M.D., Maryland Hospital for Insane, Catonsville. "The Etiological Relation of Pelvic Disease to Insanity in Women."

Russell, J., M.D., Hamilton (Ontario) Asylum. "Insanity in its Relation to the State."

Stearns, Dr. H. P., Retreat for Insane, Hartford, Conn. "Heredity as a Factor in Etiology of Insanity."

Villeneuve, George, M.D., Longue Pointe. "The Proof of Insanity in Criminal Cases."

Wise, Dr. P. M., Albany. Title of paper not received.

OPHTHALMOLOGY.

President, EDWARD NETTLESHIP, F.R.C.S., London.

The following subjects have been chosen for discussion:

1. "Heterophoria; the Indications for and Limitations of Its Operative and Non-Operative Treatment." In connection with this subject, Dr. F. Buller, Montreal, will read a paper on "Abnormalities in the Functions of the Extrinsic Ocular Muscles."

2. "How Far Can Accurate Color Vision be Relied upon to Prevent Accidents on Railways and at Sea." In connection with this subject, Mr. T. H. Bickerton, Liverpool, will read a paper on "The Question of Color Vision in the Mercantile Marine."

3. "Antiseptics in Eye Surgery."

4. (If opportunity occurs) "On the Prevention of Accidents to the Eyes of Persons Engaged in Industrial Employments."

[The list of papers omitted.]

LARYNGOLOGY AND OTOTOLOGY.

President, GREVILLE MACDONALD, M.D., London.

The following discussions will take place: (1) "On Turbinotomy," to be opened by the President. (2) "On the Ultimate Results of Operations on the Mastoid in Suppurative Ear Disease. (3) "On the Significance of Laryngeal Paralysis.

Among those who intend to take part in the business of the Section are Drs. J. Solis-Cohen, Philadelphia; Birkett, Montreal; Chretien, Montreal; G. R. McDonagh, Toronto; D. B. Delavan, New York; Charles Warden, Birmingham, and J. W. Mackenzie, Baltimore.

[The list of papers omitted.]

ANATOMY AND PHYSIOLOGY.

President, AUGUSTUS D. WALLER, M.D., F.R.S., London.

The following have been selected as subjects for the discussions:

September 1st—"Anesthetics," to be introduced by the President of the Section (Dr. A. Waller). Among those who are expected to take part in this discussion are Drs. Shore, Cambridge; Kemp, F.R.S., Baltimore; Professor W. D. Halliburton, F.R.S., London; Drs. A. B. Macallum, Toronto; H. A. Hare, Philadelphia; G. T. Kemp, Baltimore; G. Gordon Campbell, Montreal; Kenneth Cameron, Montreal, and Richet, Paris.

September 2d—"The Best Methods of Teaching Anatomy," to be introduced by Professor Alex. Macalister, Cambridge, and Dr. F. J. Shepherd, Montreal.

September 3d—"The Causation of the Heart-beat and its Modifications," introduced by Dr. Gaskell, F.R.S., Cambridge, and Professor T. Wesley Mills, Montreal. Drs. Porter, Boston; Howell, Baltimore; Bowditch, Boston; W. Townsend Porter, Boston; A. B. Macallum, Toronto; T. Wesley Mills, Montreal; G. Car Huber, Ann Arbor, Mich., and A. P. Knight, Kingston, are expected to take part in the discussion.

[The list of papers omitted.]

Dr. Gustav Mann will send for exhibition specimens illustrating the "Minute Histology of the Liver in Active and Resting Conditions." Dr. D. A. Welsh, Edinburgh, will exhibit specimens illustrating the "Histology of the Parathyroid Glands." Dr. George Oliver will exhibit his new hemoglobinometer and hemocytometer. Drs. Leonard Hill and Barnard will exhibit a new and accurate form of sphygmometer.

DERMATOLOGY.

President, MALCOLM MORRIS, F.R.C.S.Ed., London.

A subject selected for discussion in this Section is the "Clinical and Pathological Characteristics of Vesicular Skin Diseases, Especially the Dermatitis Herpetiformis Group."

It is intended that a joint meeting should be held with the Section of Pharmacology and Therapeutics for the discussion of the subject of the "Treatment of Syphilis."

[The list of papers omitted.]

Among those who are expected to take part in the discussions of this Section are: Drs. E. B. Bronson, New York; L. D. Bulkeley, New York; J. A. Fordyce, New York; J. N. Hyde, Chicago; G. T. Jackson, New York; Stephen Mackenzie, London; A. Eddowes, London, and White, Boston.

CORRESPONDENCE.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE PENDING "CRUSADE" OF THE ANTIVACCINATION SOCIETIES—IMPROVEMENTS AT THE JEFFERSON MEDICAL COLLEGE HOSPITAL—A PSYCHOLOGICAL PUZZLE—OBSTRUCTIONS TO THE ENFORCEMENT OF THE BAKE-SHOP LAW—PROFESSORS OF THE UNIVERSITY OF PENNSYLVANIA HONORED—DR. JOHN B. DEEVER—VITAL STATISTICS FOR THE WEEK ENDING AUGUST 21ST.

PHILADELPHIA, August 21, 1897.

FROM events of the past three months it would seem that the opponents of vaccination in this city and State contemplate instituting what they are pleased to term a "vigorous crusade" against this valuable preventive measure, the movement being scheduled to begin, in all probability, within the next two or three weeks, when the vaccination by the municipal health board of all unvaccinated children seeking admittance to the public schools, as provided for by law, will furnish these amusing agitators an occasion for the ventilation of their grievances.

The organized opponents of vaccination in Philadelphia

have until very recently maintained such a tranquil condition of innocuous lethargy that the average citizen was unaware of their existence; but the meetings here during the early part of the summer of the National Antivaccination Society, in conjunction with the Pennsylvania Anticompulsory Vaccination League, and a number of other "antis" with high-sounding names and local origin have called attention to their doings, and have even stirred up the deluded members of these bodies themselves toward accomplishing something less ephemeral than the issuance of *pronunciamentos* condemnatory of the principle of Jenner and of its general application. So the several societies concerned, backed by a national fund which is reported to amount to \$50,000, propose to test the constitutionality of the compulsory vaccination law, as it applies to the pupils of public schools, and thus vindicate their beliefs, and incidentally furnish the intelligent public with some amusing reading in the daily prints. The time for taking these legal steps is almost at hand, for in the course of the next few weeks the wholesale vaccination of school applicants will be under way, and will give to the "antis" many excuses and good opportunities for beginning their threatened "crusade."

Of course, in connection with this matter, the peculiar uncertainty of forensic measures and their instability must be considered, and the power of temporary injunction be thought of, but in spite of these loop-holes one can scarcely contemplate seriously a reversal of the present vaccination law, as a result of the agitations, however elaborate, of this body of untutored obstructionists. And so the prevention of smallpox will continue, in spite of tirades, abuses, and law-suits by the contributors to the \$50,000 fund, who naturally are determined to have, in racing parlance, "a run for their money," even if nothing more definite accrues.

The removal of several of the out-patient departments of the Jefferson Medical College Hospital to the new dispensary building adjoining the old hospital marks the beginning of a policy of expansion and improvement, which has long been contemplated by the hospital authorities, but which until the present time has been rendered impossible through lack of funds. For many years the facilities of the institution have been taxed to the utmost in order to properly care for the large and constantly increasing number of patients, so that the present step, which has finally become imperative, has accomplished much in relieving the congestion at the Sansom street hospital, and in furnishing the staff better facilities for both clinical and laboratory work. The present hospital will be torn down, and replaced by a modern ten-story building, erected upon property recently acquired by the trustees; work upon this structure will be commenced in the near future, most probably during the spring of next year. Hand-in-hand with the work of hospital improvement, the construction of new buildings for the medical school will progress, so that it is confidently expected that in the course of two-years' time both hospital and college will possess quarters which will be appropriate to the extent and importance of their work.

One of those curious psychologic puzzles which are so

frequently heralded as "trances" by the daily newspapers is at present attracting a share of the public attention in this city. The subject is a young girl, who, until the beginning of the seizures some six months ago, always enjoyed apparently good health. A few days prior to the commencement of the attacks, the mother of the child noticed that she became listless and apathetic, and refused to take food; she then passed, her parents declare, into a state of what from the descriptions given seems to have been catalepsy lasting for more than two weeks, from which it was impossible to arouse her. Finally she was awakened from the condition, and the mind partially regained its suspended activity, but only temporarily, for the ecstatic condition soon came on again, and has alternated with lucid intervals for the last six months. At present, the girl's condition is said to warrant a grave prognosis.

The wholly unique spectacle of a police magistrate declaring upon the constitutionality of a law has been recently furnished in this city by the decision of one of the city police-court "judges" that the present laws regulating the inspection of bake-shops are unconstitutional, and by the discharge of the defendant, although it was clearly proved that he had broken the law both in letter and spirit. The bake-shop law has been in effect for scarcely three months, but during this short time the beneficial effects of its enforcement have been shown in the radical changes wrought in the sanitary condition of many formerly disease-breeding and filthy bakeries. The law has been literally interpreted by the inspectors, and the committing magistrates, with the exception noted, have not been lax to do their duty in connection with the measure, so that it is sincerely regretted that the present obstruction has arisen, although the decision in question will have no effect whatever upon the work mapped out by the State Factory Inspection, and prosecuted under the advice and instructions of the Attorney-General of the State. Whether a police-justice is empowered to decide the validity of a legal measure passed by the Legislature is a question to be further determined by the proper courts, and this cannot be done too quickly.

Dr. Edgar F. Smith, Professor of Chemistry in the University of Pennsylvania, has been elected one of the vice-presidents of the Association for the Advancement of Science, which met in Detroit during the past week. This society has also honored another member of the University faculty by electing Dr. Lightner Witmer a fellow in anthropology, in recognition of his labors in aiding the advance of this branch of science.

Dr. John B. Deaver sailed for Europe on August 18th, intending to remain abroad for three months. He intends to spend the greater part of this time on the Continent.

The total number of deaths in Philadelphia for the week ending August 21st, was 430, an increase of 24 over those of the preceding week. Of the whole number of deaths 190 were of children under five years of age. There were 22 deaths from diphtheria, and 75 new cases; 3 deaths from scarlet fever, and 49 new cases; 14 deaths from enteric fever, and 58 new cases. There was a decrease of 20 as compared with last week in the total number of cases of contagious diseases reported for this period.

OUR VIENNA LETTER.

[From our Special Correspondent.]

DEATH OF DR. JOHANN LERCH—THE PREVALENCE OF THE ECHINOCOCCUS IN DALMATIA—A MECHANICAL METHOD FOR THE DIFFERENTIATION OF DUHRING'S DISEASE AND PEMPHIGUS—DYSMENORRHEA AND AMENORRHEA TREATED BY MEANS OF EXERCISE—INTEREST IN THE NEUROLOGICAL CONGRESS AT BRUSSELS IN SEPTEMBER.

VIENNA, August 8, 1897.

THE recent death of Dr. Johann Lerch has called forth a number of tributes from the medical press of Vienna to this the last of the distinguished members of the University faculty who took a prominent part in the struggle for constitutional liberty in 1848. Dr. Lerch was then the dean of the medical faculty, and it was at his initiative that the student body was organized, in conjunction with the faculty, into a thoroughly united society, to act as a unit during the troublous times. It was at his suggestion, also, that the students were provided with arms and so enabled to play an effective part in the struggle which finally secured certain popular rights, even if it did not accomplish all that its projectors hoped for. Austria is not the only country whose physicians have been leaders in the cause of popular liberty, and it will be interesting to the profession to realize that, while another of their number who was ready to sacrifice self, fortune, and honor for others is gone, it is only after a long and honored life.

How dangerous unguarded association with dogs may be is illustrated by a recent report of the prevalence of echinococcus disease in Dalmatia, a rather out-of-the-way province of the Austrian Empire, the inhabitants of which are noted for anything but cleanliness. Two physicians report the occurrence of forty-six cases within seven years in the hospital of which they have charge—an extremely large number, considering the rarity of the disease elsewhere. As is the case in Iceland, where, in the graphic words of an English medical visitor, the dogs share the couches of the inhabitants, and the children exchange caresses and echinococci with them in the morning, the prevalence of the echinococci in human beings is attributed to careless handling and playing with dogs, and failure afterward to take the simplest precautions of cleanliness before eating, thus carrying the ova into the digestive tract.

Curiously enough, in this report the cases are about equally divided between men and women, there being twenty-four of the former and twenty-two of the latter. Inquiry at the slaughter-houses in Dalmatia brings out the fact that it is almost the rule to find slaughtered animals affected with the echinococcus, and so the affection passes on from one species to another, while a little sanitary regulation, and attention to personal cleanliness would probably wipe it out. For man, of course, the danger lies entirely in contact with the dog, but it is the inalienable birthright of every human being the world over to own a dog if he so desires. The poorer the individual possessor, and the more worthless the cur, the more inalienable is the right of possession and the more is popular feeling aroused if the right is brought into question.

Meantime, it has become the custom to think that nothing can be done in the matter, and thousands of worthless, absolutely useless, dogs are allowed to wander at large, bearing with them, especially for children, the possibility of a number of infections.

While pemphigus, which our great American dermatologist, Duhring, so ably differentiated some years ago, is very generally acknowledged by the dermatologists of the French school to be a distinct pathologic entity, it has not met with the same ready recognition in Vienna. An article in the *Wiener klinische Wochenschrift* for July 22d, by Dr. Luithlen, would seem to suggest a means by which it may be differentiated from the forms of pemphigus, with which it has usually been confounded here.

When, some years ago, in an exhaustive study of a favorite subject, Professor Neusser demonstrated the presence of eosinophiles in pemphigus blebs, it was thought that they might prove of diagnostic importance in distinguishing forms of the disease, but further study has shown that these cells occur in nearly all chronic skin conditions. Kromayer, a year or more ago, suggested that the fluid secreted by the tissues in pemphigus is of a special character, and has a specific action in separating the epiderm from the underlying cutis. It is in following up this idea that Dr. Luithlen made his observations. If a perfectly healthy bit of skin be excised and exposed to the action of the watery contents of a pemphigus bleb, the maceration which follows causes a separation of the epiderm from the cutis after a very few minutes. If the contents of an ordinary blister, produced by a burn or scald, be used instead of the pemphigus serum, the action is much slower. It may take an hour, even, for the maceration to produce the same effect. The suggestion is that this specific action will serve as a diagnostic criterion for the differentiation of true pemphigus from allied and similar conditions.

In certain of the gynecologic clinics here in Vienna, and also to a certain extent among the best private practitioners, the ordinary treatment for functional dysmenorrhea and amenorrhea in young girls is that embodied in the direction to take a certain amount of regulated exercise. Sometimes the patients are referred to a gymnasium, sometimes to medical institutions where the mode of treatment is gymnasiotherapy. The results are said to be excellent when patients have been leading a sedentary life. Some who have been amenorrheic for months have a return of their menses often within ten or twenty days after the beginning of the treatment. In some patients in whom painful menstruation has existed for years, the first period after beginning to take exercise is almost without pain. The exercises are interrupted during the menstrual period, and of course are not meant to be employed when there is a radical organic lesion or serious pathologic condition present as the cause of the trouble. One is reminded of the oft-reported benefit derived from bicycle riding in America for similar conditions. Here, however, the public has not yet reached the stage where it looks complacently on women bicyclists, and but very few of them are seen on the streets. Even for men the exercise is thought to be too severe by many of the conservative

physicians. The temptation to overdo the exercise, in the case of hitherto sedentary individuals, is too strong, and the fact that a bicyclist only realizes how fatigued he is after he has dismounted from his machine makes conservative practitioners hesitate about recommending it, lest overwork should affect heart or kidneys.

In the midst of the bustle of preparation for the meeting at Moscow, one finds that not all the interest is being absorbed by the International Medical Congress. The first meeting of the International Neurological Congress is to open at Brussels, September 12th, and the nerve specialists look forward with a good deal of interest to its proceedings. One of the principal subjects for discussion is to be general paralysis, and it is more than a coincidence that Professor Krafft-Ebing's discourse at one of the general sessions at the Moscow Congress is to be on the same subject. The etiologic connection between general paralysis and syphilis is now so generally admitted that it is probable that the results of the discussions at each congress will make it one of the universally accepted medical dogmas. Professor Krafft-Ebing's opinion, expressed very forcibly in some of the last clinics of the year, is that syphilis, either in its acquired or hereditary form, is the important causative element in at least ninety per cent. of the cases of general paralysis, and that it is the pathologic changes produced in the central nervous system as a consequence of the syphilitic toxins which lead up to the cerebral atrophy and sclerosis of general paralysis. The subject is an extremely interesting and important one, considering how large a proportion of the inmates of our insane asylums are general paralytics. It is interesting, also, as an index of how important a rôle is now assigned to venereal diseases in the etiology of subsequent nervous affections.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Tenth Annual Meeting, Held at Niagara Falls, N. Y., August 17, 18, 19 and 20, 1897.

[Specially reported for THE MEDICAL NEWS.]

FIRST DAY—AUGUST 17TH.

(Continued from page 251.)

THE SOURCE OF PUERPERAL SEPSIS

was the title of the next paper, which was read by DR. JOHN MILTON DUFF of Pittsburg.

The essayist said that the exact source in any given case is not always easy to determine; in fact, in many instances, after the most patient and careful search one is unable to find even a probable source. In cases in which the source of infection is determined, however, it generally proves to be one which might have been avoided.

Aseptic midwifery has done much to prevent the occurrence of puerperal sepsis, and, consequently, to lower the rate of mortality following childbirth. An *accoucheur* who attends a patient without observing the strictest possible aseptic and antiseptic precautions is guilty of nothing less than malpractice. Frequently, however, too

great reliance is placed upon the use of antiseptics. A well-known member of the profession said recently in the hearing of the essayist, that he felt perfectly safe in attending a patient in labor after visiting one suffering from erysipelas or diphtheria if he washed his hands thoroughly in a strong solution of mercuric bichlorid prior to entering the lying-in chamber. Such a proceeding the essayist thought most reprehensible.

The speaker then briefly reported the histories of 50 cases of puerperal sepsis which have come under his personal observation, and specified the source of infection, when discovered, in each. In 14 of these cases, the source of infection could not be traced, although 2 were instances of placenta previa. Five of the patients were attended by a midwife, and no aseptic precautions were observed. The source of infection in the remaining 31 cases was as follows: Retained placental tissue, 5; placenta spuria, or succenturiata, 1; attending physician had previously visited a patient ill with erysipelas, 1; putrid fetus, 4; physician had previously dressed an abscess in another patient, 1; laceration of cervix and perineum, 3; putrid blood clots, 2; diphtheria case in same house, 1; acute gonorrhea in husband, 1; protracted labor, due to shoulder presentation, with sloughing of vaginal walls and cervix, 1; retained membranes, 1; tonsillitis in attending physician, 1; physician had previously dressed a case of gangrene of leg, 2; physician had opened suppurating finger, 1; mother of patient had pelvic abscess at time of latter's confinement, both being attended by same nurse, 1; decaying animal matter in cellar of house in which confinement occurred, 1; child of patient's sister had dysentery, 1; physician, a few hours previous to patient's confinement, had curetted a patient for incomplete abortion, 1.

DR. A. GOLDSPOHN of Chicago said: This paper is a most valuable one, as it calls attention to the fact that the principal source of infection in puerperal sepsis is from without, and not necessarily from the unclean surroundings of the patient, as a woman may be confined in a stable by a competent and cleanly attendant without bad results, whereas another may be delivered amid the best surroundings and may develop sepsis if the physician or other attendants do not observe aseptic precautions. The most dangerous form of infection is that by streptococci, but, fortunately, this occurs only in about four per cent. of cases. Infection by the colon bacillus and other micro-organisms is more frequent, but less dangerous. The presence of sewer gas undoubtedly is often an important factor. Many obstetricians advocate giving a vaginal douche before labor, but this should not be done if the attendant has reason to suppose that the vaginal secretions are healthy. Nature has provided a puerperal woman with copious vaginal secretions, and the one per cent. of lactic acid contained in this secretion is sufficient to kill pathologic germs in a great majority of instances. If, for any reason, this secretion is not of a healthy nature previous to labor, a douche of a 1-2000 mercuric bichlorid solution is indicated.

DR. SAMUEL MCMURTRY of Louisville, Ky., said that the number of deaths from puerperal sepsis continued to be so large that the subject should continue to be dis-

cussed in all its bearings until the importance of the possibility of its being prevented should be impressed upon the mind of every practitioner. He agreed with the first speaker that the condition is not a pathologic entity, but is a mixed infection, and should be treated as such. Milk fever, so-called, is a mild degree of sepsis, and its symptoms are liable to be overlooked, and its importance as part of a general pathologic condition underestimated.

DR. C. G. CUMSTON of Boston said that gonorrhea in the female is as difficult to cure as when occurring in the male, and that in the case of a pregnant woman in whom former infection is suspected cultures from the peri-urethral glands should be made in order that this source of sepsis might be eliminated if found to be present. He referred, also, to the numerous cases of puerperal sepsis in which the bacterium coli has been demonstrated in the uterine mucous membrane.

DR. J. F. BALDWIN of Columbus, Ohio, said that the worst cases of puerperal sepsis which had ever come under his observation presented no clinical symptoms whatever in the vagina. In three instances of sepsis during the puerperium the source had been traced to the appendix. These probably were due to the presence of the bacterium coli. The speaker then related the histories of several cases in which every possible precaution against sepsis had been observed, yet the patients died, no cause for infection being ascertainable. He said that the practice of merely dipping the hands into a mercuric bichlorid solution previous to examining a woman in labor was a reprehensible one, and could not be too strongly condemned. Thorough application of soap and hot water, with vigorous and long-continued use of a nail-brush would produce far better results, although thorough soaking of the hands afterward in the bichlorid solution would make assurance doubly sure.

With reference to the paper read by DR. LONGYEAR, the speaker thought a valuable and as yet uninvestigated field had been opened. The possibility of sepsis during the puerperium being due to infection by the Klebs-Löffler bacillus must set every obstetrician to thinking, and the strides taken during the past two years in the serum-therapy of diphtheria made it reasonably certain that by the early use of antitoxin the condition might be easily arrested and cured. If subsequent bacteriologic examination proved the infection to be due to another cause no harm would have been done by the employment of the remedy. He said that Jacobi of New York has claimed that peroxid of hydrogen in full strength is too irritating for application to the throat, and he questioned if the same is not true in the case of the vagina, especially when the canal is inflamed.

DR. POTTER said the recognition of the fact that puerperal sepsis was not an entity, but a complex pathologic condition, had led to the great improvement in methods of treatment which now prevail. While a maternity hospital formerly was looked upon by the laity and general practitioner as the most dangerous place in which a woman could be confined, such an institution now is considered the safest on account of the rigid adherence by the attendants to aseptic principles.

DR. WRIGHT of Toronto agreed with Dr. Baldwin in the importance of the use of hot water, nail-brush, and soap by the obstetrician, and said that at the Burnside Lying-in Hospital, Toronto, he is in the habit of impressing upon the attendants the importance not only of asepsis, but of antiseptics. Printed rules for washing the hands, and for the preparation of catheters and all else to be used in the vicinity of the patient, are posted conspicuously, and are strictly adhered to, but in spite of these precautions cases of sepsis and death have occurred. Two deaths were traced to inconsiderable lacerations of the perineum. Assistants at a confinement are taught to consider the immediate repair of a laceration as of the highest importance. At this hospital, 530 consecutive deliveries have occurred without a death.

DR. EDWIN WALKER of Evansville, Ind., said that the onward progress of midwifery has been in accordance with the progress of aseptic technic. Douching will not clean out an infected uterus, but if the mucous membrane of the cavity is thoroughly dried the habitat of the germs is made unsuitable for their growth. Hirst thinks that in two cases of puerperal sepsis occurring at the University Maternity, Philadelphia, the infection was directly traceable to the employment of intra-uterine douches.

The PRESIDENT said the fact is generally accepted that the causes of puerperal sepsis are: (1) gonorrhea, (2) retained placental tissue or membranes, (3) dirty hands or instruments, (4) laceration of the perineum improperly treated, and (5) intra-abdominal disease or tumors. He cited a case of strangulated dermoid cyst of the ovary as an illustration of the last-named cause. He has met with two cases of hydatid mole of the uterus during the past year. These cases are very difficult to treat, and the patient is peculiarly liable to the development of sepsis. He had seen several cases such as described by Dr. Longyear, in which a grayish membrane was present on the vaginal walls and cervix, but had never been able to determine that such was diphtheritic. He claimed that Dr. O. W. Holmes was wrong in teaching that infection in every case is carried by the physician, as there is no danger to the patient if the physician takes a hot bath, changes his clothing, and observes proper aseptic precautions, even if he has immediately before attended a case of sepsis or performed a major surgical operation. The speaker did not approve of the use of the sharp curette in cases of puerperal endometritis, as the instrument merely defeats the efforts of Nature to build up a limiting wall and exposes a fresh, absorbing surface.

DR. ALBERT VANDER VEER of Albany considered Dr. Longyear's paper one of the most valuable contributions that had ever been made to a proper understanding of the sources and types of puerperal infection. A bacteriologic examination of the vaginal secretions in all cases is of the utmost importance, but it must be carefully carried out in order to avoid the possibility of making a wrong diagnosis. He wished that a copy of Dr. Duff's paper might be sent to eighty per cent. of all the physicians of this country who have been practising more than ten years, as a perusal of it would convince them that in a

vast majority of instances puerperal sepsis is preventable.

DR. GOLDSPOHN said that the gonococcus has been said to be the most frequent cause of puerperal sepsis, but that this view is erroneous, as its presence is a predisposing rather than an exciting factor. No case is on record as having been due primarily to this germ.

In closing the discussion, DR. LONGYEAR said that in puerperal sepsis the important fact to determine is the *type* of micro-organism producing the condition, so that appropriate treatment may be instituted at the earliest possible moment.

The next paper, entitled

PUERPERAL TOXEMIA AND ITS TREATMENT,

was read by DR. ADAM WRIGHT of Toronto. He said that the offending toxins are present in these cases in the blood, liver, and muscles, and that the slightest variation from health during the progress of pregnancy should give rise to suspicion. Albuminuria often is the last symptom to appear, and in many instances does not appear at all. Charpentier and others have recommended an exclusive milk diet in cases of toxemia of pregnancy, but as milk is so distasteful to many patients, and is always constipating, its exclusive use is to be avoided. Such a diet is appropriate for infants and calves, but not for adults. Leo has shown that such a diet in the case of adults is harmful rather than the reverse.

The essayist is in the habit of allowing such patients to use milk, buttermilk, or kumyss, as taste dictated, tea once a day, lemonade, bread and butter, dry toast, arrow-root, rice, vegetables of all sorts, especially greens, and a small amount of potato. Meat is proscribed. Mineral waters of different kinds are often most agreeable to these patients, and are allowed in reasonable quantities. Hot breads and pastry are never allowed.

The routine treatment at the Burnside Hospital, Toronto, when symptoms of toxemia develop is as follows: The urine of the patient is examined, and, whether or not albumin is found, one ounce of Epsom salts is given, which is followed at intervals of a few hours by three doses of the salt of half an ounce each. An enema is then given, and, in some instances, a dose of calomel. This treatment causes the patient to have from eight to fourteen evacuations of the bowels during twenty-four hours. The patient is encouraged to drink large quantities of water, and when the unfavorable symptoms disappear, the administration of salts is discontinued unless at least two stools are obtained daily.

The free exhibition of magnesium sulphate removes noxious elements which otherwise would be absorbed from the intestinal tract, and draws large quantities of serum and its contained toxins from the circulation without disturbing or lessening the blood-globules. It thus aids the blood in getting rid of the poison, and has a beneficial effect upon the kidneys. A woman may be purged in this way during two or even three months prior to confinement without becoming anemic; on the contrary, this treatment will improve the condition of the blood. A daily warm bath should be given, and the kidneys treated only by means of copious administration of water, plain

or mineral. The uterus should not be emptied of its contents until this treatment has been fully and conscientiously carried out.

TREATMENT OF PUERPERAL ENDOMETRITIS BY THE CAROSSA METHOD

was the title of the next paper, which was read by DR. EDWARD J. ILL of Newark, N. J. The essayist said that early in the winter of 1896, a pamphlet, entitled "Eine neue Methode der Behandlung des Kindbetts-fieber mit durchsplagenten Winkung" was published by K. Carossa, which appeared to contain such valuable suggestions in the way of treatment of puerperal endometritis that he resolved to give it a trial. The method consists in irrigating the uterine cavity with alcohol, the cavity being previously packed with gauze in such a way as to admit of the alcohol reaching every part of the surface. A catheter is first introduced to the fundus and gauze is then packed lightly about it. A funnel is attached to the protruding end of the catheter through which a twenty to twenty-five volume per cent. solution of alcohol is poured so as to flow into the gauze. The quantity of the solution used is from 30 to 50 c.cm. every hour, day and night. In from three to six days the gauze is removed.

The originator of this method presented certain claims regarding its efficacy, which the reader was unable to subscribe to. Carossa attributed the good result obtained in his cases to the rapid evaporation of the alcohol. The essayist had made use of the method, slightly modified, with excellent results, and recommended its further trial, especially on account of its simplicity.

DR. GOLDSPOHN said that he could not see that this method differed in any way from that of continuous irrigation. Alcohol is one of the most potent germicides known, and its absorption under the circumstances of which the paper treated, also, its systemic absorption, might possibly prove beneficial. The method is directly at variance with that recommended by Dr. Walker, in which the uterine cavity is kept as dry as possible during the course of puerperal sepsis.

In reply, DR. ILL said that the introduction of such a small amount of alcohol every two hours cannot be regarded as continuous irrigation. The object of the procedure is merely to keep the gauze which is in contact with the surfaces of the uterine cavity constantly saturated with the fluid.

DR. RUFUS B. HALL of Cincinnati then read a paper, entitled

SOME OF THE SEQUELÆ FOLLOWING SUPRAVAGINAL HYSTERECTOMY BY THE BAER METHOD.

He referred to the objections to the extraperitoneal method, and then spoke rather more in detail of total extirpation. He was one of the first to advocate and perform this operation, and had obtained excellent results from it. But it does not meet his ideas of a perfect operation; the final results are good, but there is a primary difficulty which is disagreeable. Suppuration necessarily takes place about the ligatures on the sixth or seventh day, causing a slight rise of temperature. To overcome this he uses specially prepared catgut for the liga-

tures below the peritoneum. He finds catgut unreliable during the other steps of the operation on account of the danger from hemorrhage through slipping of the knots, and so has abandoned its use.

In 1895, after seeing Dr. Kelly of Baltimore perform the supravaginal operation, with his modifications of Baer's technic, Dr. Hall adopted that method. He had operated in this way forty-six times, but was not pleased with the results. Eleven of the patients had post-operative sequelæ, due to the presence of the buried ligatures. All the patients made a good primary recovery, only one showing any signs of trouble earlier than the seventh week. This one had a discharge of pus from the vagina at the end of the fourth week. The discharge disappeared, to return again at intervals of a few days to four or five weeks, and only ceased when the ligatures were removed. The other patients suffered in a similar way, except that they did not experience any trouble from the ligatures until from four to eleven months after the operation. Within a few days after the ligatures were removed, the patients were well, and have remained so, except in two instances. These two, one sixteen and the other eighteen months subsequent to the operation, are still having trouble, as all the ligatures have not come away. He knew the suture material was not at fault as, otherwise, there would have been trouble immediately following the operation. Besides the same material was used in other operations, and no trouble resulted. He believes that a large percentage of the patients so operated upon will certainly experience this trouble. The general surgeons are abandoning the use of silk, silkworm gut, and silver wire in Bassini's operation for this very reason, and it is only logical that the gynecologist in his line of work will have to do the same. The essayist closed his paper by saying that in spite of the fault he has to find with total extirpation, he prefers it to supravaginal hysterectomy as practised by Baer and modified by others. He feels more certain of his final results with the former method.

DR. GEORGE M. HUGHES of Philadelphia then read a paper on

THE SEQUELÆ OF DEAD LIGATURES AND SUTURES.

He advocates the use of small-sized, twisted Chinese silk in all cases of operations on the intestine and appendix, and said that the trouble experienced from the introduction of non-absorbable sutures in nearly every case is due either to imperfect aseptic methods or to the fact that altogether too many sutures are inserted.

DR. CUSHING of Boston said that he has twice given up the use of catgut as a suture material in the abdominal cavity on account of the subsequent formation of of stitch abscesses, but has returned to it as he is convinced the fault lay in the manner the catgut was prepared, or that it became infected during the progress of the operation. He recommends sterilization by formalin, and thinks the strands of the catgut should be kept in separate tubes and only withdrawn when required for use. He claims that in a majority of cases panhysterectomy is preferable to supravaginal amputation, as nothing

whatever is gained by leaving a portion of the cervix *in situ*. The generally accepted idea that the cervix acts as the keystone of an arch is entirely untenable.

DR. LONGYEAR said he was pleased to hear that others condemn the use of non-absorbable ligatures. If animal ligatures are properly prepared, no bad results will follow their use. He had employed kangaroo tendon during the past nine years in all abdominal cases, with most gratifying results, but always prepares it himself.

DR. GOLDSPOHN spoke in favor of the employment of animal ligatures, and laid particular stress upon the method of preparation. He said the formalin method of sterilization is by far the best yet devised. The formalin, under the influence of heat, converts the gelatin contained in the ligature into an insoluble substance, but the ligature must not be exposed for too long a time to its action, as it will become brittle. After sterilization, the ligatures must be washed for twenty-four hours in running water in order to "deformalize" them. As the result of a large series of experiments, he now prepares the ligature material as follows: The best quality of white, German catgut is selected, and without previous soaking in ether is placed for forty-eight hours in a four-per-cent. watery solution of formalin. Then it is put for twenty-four hours in running water, boiled for three-quarters of an hour in absolute alcohol at a temperature of 212° F., or in plain water for fifteen or twenty-minutes, and then put in sterilized retainers. It should be wound upon glass spools in order to prevent swelling and shrinking.

DR. MCMURTRY referred to the relative advantages of supravaginal and panhysterectomy, and said that the ideal method is that one which saves the life of the patient and gives rise to fewest sequelæ. He favors the use of silk for buried sutures and ligatures, and has never seen bad results from its use. If the silk has been properly prepared, the peritoneum will readily take care of it, and if it is not too large or bulky, it will become encysted and, in time, will disappear.

DR. WHITBECK of Rochester said that an operator, in his opinion, should choose the ligature material which is best adapted to the exigencies of the case. He used silk with entirely satisfactory results in supravaginal amputations when the sutures were entirely intraperitoneal, but in cases in which the abdomen or cervix has been left open he has had trouble subsequently from its employment. The use of ordinary chromicized catgut frequently unsatisfactory, in his experience, but the white variety of German catgut has always proved reliable. He invariably ties three knots in the ligature, in order to prevent the possibility of slipping.

The papers were also discussed by Drs. Crocket of Buffalo, Baldwin of Columbus, and Vander Veer of Albany.

SECOND DAY—AUGUST 18TH.

DR. M. ROSENWASSER of Cleveland opened the proceedings by reading a paper, entitled

POST-CLIMACTERIC CONDITIONS SIMULATING ADVANCED UTERINE CANCER.

He commends the teaching that irregular hemorrhages

and serosanguineous discharges, whether occurring during the parturient period or long after the menopause, are good and sufficient reasons to suspect malignancy. We carefully watch for early symptoms and by their detection occasionally succeed in removing the disease while it is still local. On the other hand, we are sometimes caught off our guard when confronted by post-climacteric cases which present all the classic characteristics of advanced malignant disease. Without the same circumspection exercised in the early stages we thoughtlessly pronounce the patient beyond hope, even specifying the extreme limit of duration of life.

The text-books are deficient in not sounding a note of warning against possible errors of diagnosis during the late stages. The so-called classic symptoms may be due to other (non-malignant) conditions of the genital tract. Owing to effacement of the vaginal portion of the cervix in old age, the differential diagnosis is limited in most cases to corporeal diseases of the uterus. Before the diagnosis of corporeal cancer can be made other diseases must be excluded.

The conditions which are likely to simulate advanced cancer are the following: (1) Senile vaginitis. (2) Foreign bodies in the vagina. (3) Gangrenous Fibroids. (4) Atrophic, senile, or post-climacteric endometritis. (5) Post-climacteric pyometra. Of these conditions the last especially is apt to lead to errors. The essayist presented the details of a case of pyometra recently occurring in his own practice, and submitted abstracts of five more or less similar instances found scattered through the literature of the past seven years. In all these cases either a positive or provisional diagnosis of corporeal cancer had been made. In conclusion the author called attention to the singular fact that in the presence of the essential predisposing conditions—age, low vitality, cicatricial tissue, adhesions, chronic inflammation and irritating discharges—cases of transformation into malignant disease are either unknown or exceedingly rare.

DR. RICHARD DOUGLAS of Nashville, Tenn., then read a paper, entitled

CERTAIN CYSTS OF THE ABDOMINAL WALL,

which was confined entirely to a consideration of abnormalities of the urachus. After referring to the anatomy of the structure he first took up the consideration of vesicoumbilical fistula. These fistulæ are not very uncommonly encountered during infancy and childhood. They frequently close spontaneously. In adult life the condition is unusual. As an instance, he quoted cases reported by Freer of Washington, Schullenbach, Hoffman, and Holscher. The last named is somewhat remarkable in that it followed an attack of gonorrhea. A man, twenty-five years of age, had a stricture as a result of that disease, the atresia of the canal being so great that it was only with difficulty that a filiform bougie could be passed. From this condition he suffered during several years, when the habitual retention of urine in the bladder caused a mechanical dilatation of the urachus, which set up an ulcerative process and caused perforation of the umbilicus through which the urine found exit. It was easy to com-

pletely evacuate the bladder through this opening by compressing the viscus above the symphysis pubis.

Usually there exists in an acute or chronic form some pronounced disease of the urethra or bladder, resulting in retention of urine or great vesical tenesmus. Suddenly there develops a tumor just above the pubis, at first of small size, distinctly circumscribed, quite hard, non-fluctuating, on account of the tenseness of the walls, and sometimes very tender. There is marked diminution in the amount of urine, and, usually, great dysuria. Nausea, vomiting, and great depression ensue. Pain over the entire lower abdomen is a constant symptom. Gradually the tumor enlarges, becomes softer, more elastic, and fluctuating. The local signs and general symptoms depend entirely upon the character of the urine which is forced backward into the urachus; if it is septic, a purulent inflammation of the walls of the urachus develops and the hypogastric tumor may closely resemble an acute abscess. There is, however, a frequent and more fortunate termination for these cases in which the tumor retains vesical connection, as by catheterization or otherwise the distended bladder is relieved, the urachus is drained into the bladder, the tumor suddenly disappears, and all pain and symptoms quickly subside.

The essayist then referred to the form of urachal cyst arising from a dilatation of the greater portion of the tube, the vesical and umbilical ends of which are closed, and reported a case occurring in his own practice. The patient was operated upon on June 20, 1896. There apparently was no ligamentous attachment between the cyst and the bladder. The cyst was removed, and an area of peritoneum extending from about three inches above the umbilicus to the symphysis and from two inches to the left of the linea alba and throughout the lumbar and iliac regions of the right side was separated from the parietes. Twenty-four hours after operation the patient became very dull, vomited freely, and was inclined to sleep. She died the following day. Upon autopsy, the entire detached peritoneum on the right side was found to be gangrenous. The peritoneum had not been stitched to the abdominal wall during the operation as it was thought intra-abdominal pressure would restore it to its former position.

CONSERVATION OF THE OVARY

was the title of the next paper, which was read by DR. B. SHERWOOD-DUNN of Los Angeles, Cal. This paper excited the most animated and general discussion of all read at the meeting. The essayist said that Brown-Séquard believed and taught as a principle of physiology that every gland, whether or not provided with excretive ducts, gives to the blood a certain useful principle, the absence of which is felt and made apparent after their extirpation, or the destruction or modification of their functional activity by disease. The importance of this theory, if it is based upon fact, cannot be overestimated; and if its truth be proved and generally accepted, it certainly will have a modifying influence upon the frequency with which the ovaries are extirpated. From observations based upon the cases of 100 women operated upon at the Broca and St. Louis Hospitals, Paris, the essayist said

that when the patient had prematurely lost both ovaries, 78 per cent. subsequently suffered a notable loss of memory, 60 per cent. were troubled with flashes of heat and vertigo, 50 per cent. evinced a change in character, becoming more irritable and less patient, some even being subject to violent and irresponsible fits of temper, 42 per cent. suffered more or less from mental depression, and 10 per cent. were so depressed as to verge upon melancholia. In 75 per cent. there was a diminution in sexual desire, some claiming that they experienced no sexual pleasure at all. Thirteen per cent. were not relieved from the pain from which they had suffered, 35 per cent. increased in weight and became abnormally fat, and some complained of a diminution of the power of vision. Twelve per cent. developed a change in the tone of the voice, it becoming heavier and more masculine in quality, 15 per cent. suffered from irregular attacks of minor skin affections, 25 per cent. had severe headaches, as a rule, increased in intensity at the catamenial period, 25 per cent. complained of the occurrence of nightmare, more or less constant, and about 5 per cent. suffered from insomnia. In a few cases there existed a sexual hyperexcitability not present prior to castration. A few patients, also, developed gastric reflexes and marked indigestion. All of these symptoms or changes were more marked in women under thirty-three years of age.

The essayist then said that any skepticism which he may have entertained regarding the theory of ovarian secretion and its usefulness and necessity to equipoise of the entire system had been entirely dissipated by the results of experiments made with ovarian substance, or ovarine, in patients who have lost both ovaries, or were suffering from troubles which in a greater or less measure were due to a diseased condition of an ovary. He gave the following accumulated evidence in support of his views:

1. Statistics show functional troubles to be more constant and intense in women who have lost both ovaries by operative interference.
2. There is little, if any, modification of these disturbances when the uterus is left in place and both ovaries removed.
3. These troubles are notably less when the uterus is removed and the ovaries left *in situ*.
4. By the favorable results of the experiments of Jayle, Mainzer, Mond, Chrobak, and Muret, in addition to his own, in the administration of ovarian substance, or ovarine, to patients suffering from various forms of disturbance, more or less intense, following double oöphorectomy, and, equally, those suffering from functional difficulties due to ovarian diseases.

He is in the habit of giving these patients 2 grains of ovarine, in capsules, daily. He deprecated the wholesale sacrifice of both ovaries, and made a plea for more conservative methods. Ignipuncture, according to the method of Pozzi, has given the most satisfactory results in his hands.

Following the discussion of this paper, the President of the Association, DR. JAMES F. W. ROSS of Toronto read an address, taking for his subject

SURGERY AND FACTS.

After thanking the members for the honor of his election, and referring feelingly to the pleasant association with them during the past ten years, he said, in part:

"Our work in this Association is confined within the diaphragm, the perineum, and the abdominal walls. We are met together to cultivate and promote a 'knowledge of whatever relates to abdominal surgery, obstetrics, and gynecology.' You will be called upon, during the session, to express your views and to criticise or support the views of others. We do not wish to deal with questions that are already settled but with those that are unsettled. Though the criticism should be friendly, I trust that it will be severe; no rash statements should be allowed to go from this Association unchallenged.

"I would like for a few moments to call your attention to some unsettled questions: First, let us consider the question of peritonitis. Are we able to do more to save the lives of patients suffering from peritonitis in its acute form than we were ten years ago? Are we not but little better off with all our antiseptic and aseptic washes, gauze and tube drains, and purgatives? I am satisfied that surgery can carry us no further when battling with this disease. Something else must come to our assistance. Perhaps, it may come through serum-therapy or through our materia medica in the form of an antidote. We know that a poison is formed, that it is rapidly absorbed into the system and rapidly reformed. We know that we may wash it out but that we are unable to prevent its reformation. We know that in some cases we are able to minimize its effect by using the two drainways, namely, the drainage-tube and the intestinal canal. But in spite of this drainage large numbers of patients die. I intend to try direct venous infusion of salines. The sulphate of magnesia seems to produce a peculiar effect in some of these cases. We know that ordinary salt is a preservative of meat and other albuminous materials. It may be that absorption of these salines into the blood may act as a harmless antiseptic and may destroy the ptomain poison present. I am speaking now, of course, of the peritonitis that we are unable to prevent, or peritonitis from contamination from within. When least expected the *post-mortem* examination will frequently reveal some hidden source of internal contamination."

DR. HERMAN E. HAYD of Buffalo then read a paper, entitled

RECENT EXPERIENCES WITH VENTROFIXATION.

He said that the Alexander operation and the various intraperitoneal operations upon the round ligaments have relieved and cured a great number of women hitherto doomed to more or less chronic invalidism. Ventrofixation, in properly selected cases, also has proved of benefit, but an operation which forcibly fixes an organ in an unnatural position cannot be deemed an ideal one. However, because such fixation of the uterus sometimes offers serious impediment to delivery, it is no reason why the operation should be relegated to oblivion as it is still applicable for the relief of that large class of suffering women

who have passed the child-bearing period who most frequently are the victims of procidentia uteri.

The essayist had made use of buried silkworm-gut sutures in his earlier operations but now is satisfied that a suture material which will maintain the organ in its new position during a few weeks is all that is necessary, as at the expiration of that time sufficiently strong adhesions will have formed to hold it. He has employed chromicized catgut, No. 3, in his last six cases, passing the sutures through the anterior surface of the uterus, just beneath the peritoneum, instead of through the fundus.

WHICH IS THE PREFERABLE OPERATIVE METHOD OF HOLDING THE UTERUS IN POSITION?

was the title of the next paper, which was read by DR. C. FREDERICK of Buffalo.

The essayist said that in all cases of retroversion of the uterus symptoms of the condition are not necessarily present, but a certain proportion are accompanied by hypertrophy of the organ, endometritis, leucorrhea, pain, backache, menorrhagia, metrorrhagia, and general malaise. Constitutional treatment fails to relieve a large number of patients so afflicted unless the uterus is restored to its normal position. The principal factors in the continuance of the ill effects of retroversion are found in the torsion of the contained vessels, infection of the endometrium, and defective drainage of the uterine cavity. Retroversion is the first stage of prolapse, and for this reason alone the organ should be replaced and held in position.

The operation of ventrofixation in cases of women liable to bear children is no longer practised by the essayist; he performs it only in cases of marked prolapse and when both tubes and ovaries have been removed, although in child-bearing women he has seen no bad results from it, several of his patients having had normal labors after it had been performed. His preference is given to Alexander's operation, or one of its modifications, however, in the case of women who have not yet reached the menopause, and when there are no adhesions or disease of the adnexa. Women who have never been pregnant are liable to have poorly developed round ligaments, which are prone to become detached to the anchoring sutures, and in these instances he opens the abdomen and shortens the ligaments after the method of Mann, Dudley, or Wylie. The method of the first is given the preference. He employs plain or chromicized catgut sutures in all cases. The different methods of shortening the ligaments through a vaginal incision have never appealed to him, and therefore he has not given them a trial.

TECHNIC OF THE DRY METHOD OF OPERATING

was the title of the next paper, read by DR. EDWIN WALKER of Evansville, Ind. He does not claim originality in this method, as it has been carried out by a number of operators, it has been used during several years, with good results, and consists, essentially, in not permitting a drop of water to come into contact with the field of operation, from the time the first incision is made until the wound is closed. Particular attention is paid to cleanliness and the sterilization of instruments and dress-

ings. Dry gauze pads are used to remove pus or other secretions.

DR. WALTER B. CHASE of Brooklyn then read a paper, entitled

SURGICAL SHOCK AND HEMORRHAGE, WITH SPECIAL REFERENCE TO PREVENTION AND TREATMENT.

After referring at length to the differential diagnosis of shock and hemorrhage following surgical operations, the essayist said that the treatment of shock divides itself into those measures which are preventive and those which are curative. The physical and mental condition of the patient bears a constant and close relation to the degree of shock likely to be induced by a given operation; therefore it is a self-evident proposition that whatever will fortify the patient in bodily and mental health, either by dietetic, therapeutic, or hygienic measures is worthy of the most careful consideration, and in elective operations time thus spent is well spent. The physical condition and functional activity of all the organs of the body should be a matter of careful and conscientious study. Bodily secretions and excretions must, as far as possible, be known, especially with reference to lithemic and uremic conditions.

The deleterious influence of shock is chiefly manifested by the nervous system and the heart. To fortify the latter organ strychnin, if practicable, should be administered during a few days prior to the operation to the extent daily of from one-twelfth to one-sixth of a grain. This drug is particularly applicable in cases of fatty and atheromatous degeneration of the heart and blood-vessels. If the arterial tension is low, with small volume, and fatty and atheromatous degeneration is absent, digitalis fulfils the indication, and should be given in moderation until its physiologic effect is apparent. In muscular weakness of the heart, the administration of one-eighth of a grain of spartein sulphate every two or three hours during twenty-four or forty-eight hours is indicated.

The alimentary canal should be absolutely empty during all elective operations, in order to limit the liability to nausea, flatulency, and impairment of intestinal peristalsis. In operations involving the peritoneal cavity it is a wise plan to require the patient to maintain a horizontal position for a period of two or more days prior to operation. The practice of leaving from one to three pints of a normal salt solution in the abdominal cavity after operation is a good one, as it prevents, to a great extent, the distressing thirst, which, of itself, is often a source of shock. The time consumed in an operation should be limited to the shortest period compatible with thorough work and proper technic. The patient should be saved from the shock of fear to the greatest possible degree. In shock accompanied by or resulting from hemorrhage, transfusion of normal salt solution should immediately be resorted to.

THIRD DAY—AUGUST 19TH.

The first paper of the day, on

PLACENTA PREVIA, WITH SPECIAL REFERENCE TO TREATMENT,

was read by DR. W. H. WENNING of Cincinnati. The

essayist said that he could offer nothing new in the way of suggestions for the treatment of placenta previa, but would refer particularly to the different methods of meeting the two principal indications, namely, to arrest hemorrhage, and to expedite labor. In the first named, each procedure has its peculiar advantages and disadvantages, and no special method is applicable for each and every case. He briefly summarized the histories of fifty cases which have been reported by different American practitioners during the past five years, and said it is surprising to note that about three times as many successes have resulted from the much condemned method of *accouchement forcé* in these cases as compared with other procedures.

The use of the tampon, rupture of the membranes, and version, were successively reviewed, and the speaker asserted that in a majority of instances reliance cannot be placed upon one of these alone, as it frequently requires a combination of all three at the proper time to bring the case to a safe conclusion. He laid down the proposition that the tampon is applicable only before dilatation of the os, rupture of the membranes after the onset of labor pains, and version after the os is dilated or dilatable. Each of these procedures is subject to certain modifications, and frequently it is difficult to determine when to abandon one and resort to the other. He insisted that if a tampon is inserted into the vagina a patient must never be left for a moment until delivery is complete.

Rupture of the membranes, as a rule, should be resorted to only when the os is sufficiently dilated to allow the head to press upon the cervix, or the hand to be introduced for the purpose of version. Internal version is the oldest and best-known method of delivery in placenta previa, and is most effective when the os is dilated or dilatable. *Accouchement forcé* is a dangerous procedure as it is very apt to cause laceration and even gangrene of the cervix, and is never justifiable unless no other means can be resorted to in order to terminate labor and save life.

COMPLETE HYSTERECTOMY AFTER INJURY DURING PARTURITION AND CÆSAREAN SECTION; WITH REPORT OF CASES,

was the title of the next paper read by DR. JOSEPH H. BRANHAM of Baltimore.

The first case reported was that of a woman, aged twenty-four years, who, when a child, was run over by a heavy wagon, sustaining an injury to the pelvis. During 1894, and again in 1895, she was delivered of a healthy child, each labor being difficult and prolonged. On July 15, 1896, she was again in labor, and when the speaker was called, after an interval of twelve hours, the child being alive and vigorous it was decided that the performance of Cæsarean section, for many reasons, was indicated. This was carried out, and a female child in good condition extracted. The patient died two days later from septic infection, directly traceable to previous vaginal examinations made by a midwife.

The second patient, a colored woman, had had five children and five miscarriages, all the labors having been protracted and requiring instrumental aid. Pelvis small, but presenting no marked deformity. Confinement occurred October 3, 1896. Tarnier forceps necessary to

complete delivery. The speaker first saw the patient on the following day. An extensive tear involving the vagina at its junction with the uterus on the left side, and a small wound on the right side, were discovered. The abdomen was greatly distended, and the pulse 120 to the minute and hardly perceptible at the wrist. On account of the great quantity of blood in the pelvic cavity, and the consequent probability of its giving rise to septic infection, laparotomy was performed. A tear extending from the left posterior segment of the uterus, across the upper part of the vagina and anterior wall of the rectum into the left broad ligament, about six inches in length, was found. In view of the extensive injury, and probability of infection, combined with the difficulty which would be experienced in closing the wounds with the uterus in position, complete hysterectomy was performed. Iron-dyed silk was used for the sutures. Recovery was complete, except that there has been a slight discharge of pus from the vagina at intervals up to the present time.

DR. FREDERICK BLUME of Allegheny, Pa., then read a paper, entitled

DYNAMIC ILEUS FOLLOWING OPERATIONS INVOLVING THE ABDOMINAL CAVITY, WITH REMARKS ON ADYNAMIC ILEUS.

The essayist said that decided progress in the direction of diagnosis and treatment of ileus following abdominal section was made when Olshausen, in 1887, called attention in an article read before the Berlin Obstetrical and Gynecological Society, to a form of intestinal obstruction which had not yet been recognized, namely, a paralysis of the gut not dependent upon septic peritonitis. The symptoms in these cases are increased pulse-rate, normal, slightly elevated or, in some instances, subnormal temperature, and vomiting. Two or three days after the performance of the operation, or even later, the symptoms of collapse manifest themselves, the pulse becomes rapid and feeble, the abdomen more and more distended, and retching and vomiting more frequent. Neither gas nor feces are expelled from the rectum. Death ensues between the fourth and tenth day, and is the result of general systemic intoxication from absorption of the decomposed intestinal contents.

In a recent article Engström reviews the literature of the subject and arrives at the conclusion that paralysis of the intestine can and does occur after operations involving the abdominal cavity without infection having taken place at the time of operation. Eventration and prolonged manipulation of the bowel are the most potent etiologic factors, causing irritation of the nerves of the mesentery and gut-wall, and leading to changes in the circulation. From his own experience Engström is able to confirm the statement of other observers that a paresis of the intestinal wall can be produced by the administration of strong saline purgatives, and it appears to be by no means improbable that, as a consequence of their use, a weakened condition of the gut-walls is produced prior to the operation. He looks upon the increased susceptibility of the nervous system, often so marked in patients about to undergo a surgical operation, as a predisposing etiologic factor.

The essayist said that the differential diagnosis between post-operative intestinal obstruction and dynamic ileus is practically impossible, but that in either case the only chance for the patient is afforded by speedy surgical interference. The surgeon, however, must distinguish between these forms of ileus and the very obstinate form of constipation so often met with, and so difficult to overcome, after operations in the abdominal cavity. The occurrence of fecal vomiting is not always a pathognomonic sign of ileus, as this vomiting sometimes occurs under other conditions and where there exists no indication for surgical interference.

THE ADMINISTRATION OF PHOSPHATE OF STRYCHNIA DURING GESTATION

was the title of the next paper, which was read by DR. W. B. DORSETT of St. Louis. The essayist said that while strychnin, either alone or in combination with iron, quinine, etc., has been administered with great success for many years as a tonic in anemic conditions, but little attention has been given to it as a tonic in anemia associated with pregnancy. Constipation, and the consequent occurrence of ptomain poisoning, as evidenced by languor, dizziness, and general malaise, aside from kidney lesions, is probably one of the most serious conditions with which the physician has to deal during the course of pregnancy, and now and then cases arise in which the attendant's ingenuity is severely taxed in making choice of a remedy to be used continuously during that period. The speaker has given a fair trial to strychnin in combination with iron or the bitter vegetable tonics, under these circumstances, and finally has adopted the use of the phosphate, in pill form. One one-hundredth of a grain is given after meals, which dose at times is doubled, as the conditions present may indicate. By this means a patient is built up and put in a good condition to pass through the ordeal of labor. The uterus promptly contracts after the completion of the third stage, and the use of ergot may be entirely dispensed with.

DR. A. GOLDSPOHN of Chicago then read a paper, entitled

THE FATE OF THE OVARIES IN CONNECTION WITH RETROVERSION AND RETROFLEXION OF THE UTERUS.

He said his subject did not include those less frequent instances of ovarian descensus which occur without backward deflection of the longitudinal uterine axis, primarily from pathologic processes which either have increased their weight or have left their ligamentary supports relaxed or elongated, so that one or both ovaries drop downward and inward into the median line of the pelvic canal, temporarily or permanently, even while the uterus remains in normal position. He drew attention only to one, the most prolific cause of descent of the ovaries—that met with in cases of a thoroughly retroverted uterus, and referred to the traumata which the ovaries experience in the majority of instances, to a variable degree, in their helpless association with the condition. The one substantial support of the ovary, which holds when the other attachments readily yield, is the utero-ovarian ligament. This

holds the abdominal end of the tube in proximity to the ovary, its edge carrying the *fimbria ovarica*, and it serves, in common to both the ovary and ampulla of the tube, as their lateral and upper suspensory ligament, finding its attachment in the posterior portion of the iliac fossa. An exact and typical location for the ovary has not yet been agreed upon; it is an extremely difficult matter to feel or to see its attachments in the living, and almost equally difficult to find them unmodified even in fresh and skillfully prepared cadavers. The wholesome view of B. S. Schultze, chiefly based upon extensive acute clinical observations, is that the ovary does not normally hang downward (pendant) from its hilum, but is held resting upon it by the tension of the ligaments attached to its ends. These also hold it in close apposition to the mesentery of the tube (broad ligament) which arches over it and forms a recessus for it (*ala vesperilionis*).

What are the forces which influence the position of the uterus and its adnexa? Substantially, they are as follows:

(1) A variable degree of tension peculiar to the interior of each hollow viscus. (2) Gravitation of the abdominal viscera, which is zero at the diaphragm and attains its climax in the median line of the pelvic cavity. (3) The most important and powerful, a general intra-abdominal tension created, according to Swiecicki, by sixteen abdominal and pelvic muscles. This force is greater in the erect than in the horizontal posture; it is greater during exertion than while standing placidly, and while it is everywhere equalled in the abdominal and pelvic cavities, still a temporary physiologic displacement or crowding downward of abdominal viscera occurs by virtue of proportionately greater power vested notably in the diaphragm and other muscles of the upper part of the abdominal parietes. The consequent reduction in lumen of the abdominal cavity and temporary recession of viscera toward the pelvis is the principal factor in abdominal pressure. It is the greatest force that is anywhere exercised in the interior of the human trunk.

That retroversion and retroflexion of the uterus are the most frequent and most potent cause of ovarian descensus is conceded by every author on that subject. It induces diseases of the ovaries in the following manner:

1. In most instances of retroversion the outer or upper suspensory (spermatic) ligaments of the ovaries have already been relaxed by the same cause which in most cases leads to retroversion, *i.e.*, pregnancy, which has been followed by subinvolution not merely in the uterus and its ligaments, but also in the upper suspensory ligaments of the ovaries which yielded by far the most when the ovaries made their ascent with the pregnant uterus into the abdomen. In those cases, on the other hand, in which the ovaries have not thus already practically lost the support of their upper suspensory ligaments, those yield more or less readily when the fundus goes over backward and downward, because of the greatly superior strength of the utero-ovarian ligaments.

2. Being now removed from their retreating nooks on the anterolateral walls of the pelvis, the ovaries become subject to the forces from above which move them still nearer, when possible, to the median line of the pelvis, back of

the retroverted uterus. In this descent they become arrested, in most cases, by the uterosacral folds or ligaments. This is the first degree of descensus. Each lies in a pocket at the side of the supravaginal portion of the cervix and the corpus uteri. One or both may pass over the uterosacral folds and slip down and forward to the bottom of the cul-de-sac of Douglas, thus accomplishing the second or complete degree of descensus.

The evils which attend this descent and abnormal position are of two kinds—partial venous stasis, and mechanical traumata. The torsion of the broad ligaments, in retroversion of the second degree, amounts to at least ninety degrees, but in addition to this the venous current from the ovary is obstructed by torsion and traction upon its hilum. Regarding traumata, an ovary in extreme descensus lies as in a vice which acts irregularly, but very many times daily. Every forcible exercise of intra-abdominal pressure crowds the retroverted uterus down upon it from above, and every filling of the sigmoid and rectum bruises it from below. Normal coitus is scarcely possible without marked compression of the female testicle and excitation of suffering.

The pathologic changes in such ovaries, resulting from the constant passive hyperemia and innumerable traumata inflicted upon them, are: (1) Hematomata in Graafian follicles and corpora lutea. (2) Edema. (3) Connective-tissue hyperplasia. (4) Chronic oöphoritis, leading to multiple cystic follicular degeneration, usually in parts of an ovary and cirrhotic changes in the remaining parts. (5) Even peri-oöphoritis, and eventually peritoneal fixation, may occur without infection, according to Saenger.

The essayist's conclusions were as follows:

1. In all cases of retroversion and retroflexion of the uterus a knowledge as to the location, mobility, and general physical condition of the ovaries should comprise an essential part in the diagnosis, as largely determining the urgency and nature of the treatment.

2. The welfare of ovaries in general demands such a degree of anterior inclination of the longitudinal axis of the uterus as will enable intra-abdominal pressure to bear upon the posterior surface of the uterus, and thereby to act in unison with its other supports to retain it and its adnexa in normal position and function.

3. Inasmuch as in the female pelvis, as well as elsewhere in the human body, the natural and considerable abilities of healthy tissues to defend themselves against microbic invasion (infection) are lowered or annulled in direct proportion to any degree of mechanical embarrassment of the venous circulation in the tissues or organs, it behooves gynecologists especially to be alert in recognizing and correcting all considerable anomalies in place or posture of the female generative organs or in securing to them their normal freedom.

After the reading of Dr. Goldspohn's paper, an exhibition of pathologic specimens, with relation of histories of the same, was made by Drs. Dorsett, Vander Veer, McDonald, Price, Ross, McMurtry, and others, and the Association then went into executive session. The following officers were elected for the ensuing year: President, Dr. C. A. L. Reed of Cincinnati; first vice-president, Dr. John Milton

Duff of Pittsburg; second vice-president, Dr. W. B. Dorsett of St. Louis; secretary, Dr. William Warren Potter of Buffalo; treasurer, Dr. Xavier O. Werder of Pittsburg; members of executive council, Drs. Albert Vander Veer of Albany, L. S. McMurtry of Louisville, J. H. Carstens of Detroit, and W. E. Davis of Birmingham, Ala.

Pittsburg was chosen as the next meeting place, and September 20 to 23, 1898, as the time, the latter being subject to change. The annual dinner of the Association took place during the evening.

FOURTH DAY—AUGUST 20TH.

DR. GEORGE S. PECK of Youngstown, Ohio, read a paper, entitled

FIFTY-TWO CASES ILLUSTRATING A PERSONAL EXPERIENCE WITH THE MEDICAL AND SURGICAL TREATMENT OF APPENDICITIS.

He said that although appendicitis is one of the most important as well as treacherous diseases with which a physician has to deal, it is a fact that many are unable to differentiate it from a clinical standpoint from the condition generally known as inflammation of the bowels. A diagnosis should never be difficult if the four cardinal symptoms of appendicitis are borne in mind, namely, sudden, severe pain in the abdomen, generally of a colicky nature; second, the invariable occurrence of nausea, and, frequently, of vomiting; third, increased bodily temperature; and, fourth, localized tenderness in the right iliac region. Some patients may have diarrhea, while others may be constipated. It is not essential that a mass be detectable, or that the rectus muscle be rigid, in order to confirm the diagnosis.

An early operation is always advisable. Certain surgeons advise simple incision and drainage, in the suppurative form of the disease, and the removal of the appendix subsequently, while others advocate the breaking up of existing adhesions and excision of the organ at once, and report good results from this procedure. Each case of the disease is a law unto itself, yet the speaker believes that in a vast majority of cases it is the duty of every surgeon to perform a radical operation at the first sitting. In the last three cases in which he has operated, and in which pus was evacuated, he separated adhesions, cleansed the cavity with hydrogen peroxid and distilled water, flushed the entire abdominal cavity, inserted a glass drainage-tube down to the appendical stump, and closed the incision. Two of the patients were discharged within three and the remaining one within four weeks of the date of operation.

He then reported the series of 52 cases in detail, 35 of the patients having been treated surgically, and 17 medically. Of the former, 25 were males and 10 females, the total number of deaths being 7, 4 males and 3 females. The cause of death in 5 instances was septic peritonitis; in 1, convulsions, and in 1, exhaustion. In 22 cases in which the appendix was removed the organ was gangrenous and perforated. In 13 cases an incision was made and the pus evacuated, and in 4 the patients had recurrent attacks after incision and drainage. All these cases, with one exception, were of the acute suppurating type of the disease, and all the patients received medical treatment

for a period varying from two to twenty days prior to operation.

Of the 17 cases in which medicinal treatment alone was instituted, 9 were males and 8 females. There were 9 deaths—of males 2, of females 7. The cause of death in 4 instances was septic peritonitis; in 4, rupture of the abscess into the abdominal cavity, and in 1, unknown.

DR. L. S. MCMURTRY of Louisville then read a paper, entitled

THE OPERATION ITSELF IN APPENDICITIS,

which will appear in conjunction with other papers read at the meeting in forthcoming issues of THE MEDICAL NEWS. Installation of officers-elect then took place, and the meeting was declared adjourned.

THERAPEUTIC HINTS.

For Gastric Indigestion.—In cases of gastric indigestion accompanied by what is commonly called torpidity of the liver, the following combination will be found of great value:

℞	Ac. nitromuriat. dil.	. . .	℥ ss
	Tr. nucis vom.	. . .	℥ ii
	Liq. potass. arsenitis	. . .	gtt. lxxii
	Ess. pepsin, q. s. ad.	. . .	℥ vi.

M. Sig. Dessertspoonful thrice daily after meals.

For Chronic Constipation.—An excellent combination in pill form for chronic constipation is the following:

℞	Ext. nucis vomicæ	. . .	gr. vi
	Ext. belladonnæ	. . .	gr. iv
	Ext. colocynth, comp.	. . .	gr. xlviii
	Aloes (purified)	. . .	gr. xxiv.

M., and ft. pil. No. xxiv. Sig. One at night.

"Rhinitis."—The pills which are so generally sold at drug stores under the name of "Rhinitis," and which are highly to be recommended for incipient "cold in the head," are made up as follows:

℞	Camphoræ	. . .	gr. ¼
	Ext. belladonnæ fl.	. . .	gr. ⅙
	Quinæ sulph.	. . .	gr. ¼.

One or two pills may be taken every three hours.

For Diarrhea.—One of the best combinations for diarrhea due to indiscretions in diet is the following, which should be preceded several hours by the administration of a tablespoonful of castor oil:

℞	Tr. opii	} aa	. . .	℥ ss
	Tr. capsici			
	Spt. camphoræ			
	Chloroformi (pur.)	. . .	. . .	℥ ii
	Alcoholis, q. s. ad.	. . .	. . .	℥ iii.

M. Sig. Teaspoonful every four hours.

For Dyspepsia.—The well-known "R. & S. Comp." mixture, than which no combination is so frequently prescribed at dispensaries, is composed of the following:

℞	Pulv. rhei	. . .	℥ i gr. xxxvi
	Sodii bicarb.	. . .	℥ ss
	Pulv. ipecac	. . .	gr. vi-viii
	Tr. Nucis vomicæ	. . .	℥ ii
	Aq. menth. pip., q. s. ad.	. . .	℥ vi.

M. Sig. Two teaspoonfuls before each meal.

NO. 10.

ORIGINAL ARTICLES.

SIXTY-FIFTH ANNUAL MEETING OF THE BRITISH
MEDICAL ASSOCIATION, MONTREAL, AUGUST
31 TO SEPTEMBER 3, 1897.

THE PRESIDENT'S ADDRESS.¹

By T. G. RODDICK, M.D.,
OF MONTREAL, CANADA;
PROFESSOR OF SURGERY IN M'GILL UNIVERSITY.

You have been welcomed to the Dominion of Canada by the noble Earl who is the worthy representative of our beloved Queen; you have been welcomed to the Province of Quebec, to which this city belongs, by our eloquent and justly esteemed Lieutenant-Governor; the Chief Magistrate of our city has given you "*Cæd mille faihthe*" in a manner in which only an Irishman with such a great sympathetic heart as he possesses can give; and now I rise to welcome you on behalf of the medical profession of Canada, and to thank you for the honor conferred upon this city and country by your presence here to-day. Would that I could find suitable language in which to thank you also for the high honor you have done me in electing me to preside at this great meeting of the British Medical Association, an honor which is appreciated none the less by the consciousness that it is not a personal matter but a compliment to Canadian medicine.

This meeting of the British Medical Association in Canada is an event which will serve still more to impress the year 1897 upon the memory of our people, the year of the Diamond Jubilee of our beloved Sovereign, Queen Victoria. In no part of her vast Empire—not even in its very heart—did her subjects celebrate the great event with more enthusiastic loyalty and devotion than in Canada, especially in this province, the home of the French-Canadians. We Canadians of both tongues love and honor our Queen. Long may she live! Deeply, too, have we appreciated here the splendid reception accorded in the old home to our Premier, the Right Hon. Sir Wilfred Laurier, whose distinguished bearing and grace of manner eminently fitted him for the important part it was his peculiar privilege to play in the magnificent ceremonies of the Jubilee. A French-Canadian, Sir Wilfred's presence in England as the chosen representative of the Dominion was an object

lesson to the Empire and to the world in the harmony existing between the two nationalities which comprise the Canadian people.

And here let me express on behalf of every representative from the British Isles, and on behalf of every Canadian present, the genuine pleasure we feel in having among us on this memorable occasion so many of our brethren from the United States. This only proves the cosmopolitan character of our profession; this is only another recognition of the unity of medicine. Legislators may squabble, the air may be filled with wild alarms, and war may appear imminent day by day, but our relations are not disturbed in the slightest degree; our interests are common—we are kinsmen in science; we go forward hand in hand, irrespective of race, creed, or color, having one intent only: the advancement of our noble profession, and through that the amelioration of the ills of mankind.

It is my privilege also to welcome the representative of another Republic, *La Belle France*, to whose gifted men of science our profession is so greatly indebted. This gentleman, who bears the credentials of his Government, and officially represents the great nation of which he is so bright an ornament, is known far and wide as the Professor of Physiology in the University of France, Dr. Charles Richet. In coming to Canada it cannot be said, nor will he feel, that he comes to a foreign country, for in the Province of Quebec he will find another France, with a delightful mingling of the old and the new, and his own beautiful language spoken with all the grace and purity of the old *régime*.

But we are further honored by the presence among us to-day of the most illustrious surgeon of our generation, Lord Lister, who stands for the rise and zenith of modern surgery. It has been well and truly said that as long as surgery is scientifically discussed Lord Lister's name cannot fail to be mentioned. We have only to compare the surgery of the time before 1873 with the surgery as practised to-day to appreciate all that he has done for the science. Can it for a moment be questioned that Lord Lister has made operative proceedings possible which only twenty-five years ago would have been considered criminal? Undoubtedly, the most powerful agency in the development of surgery in this century has been the introduction of the antiseptic and aseptic methods of wound treatment, which he initiated.

¹ Abstract.

It is, I understand, an unwritten law of the Association that the President shall not in his address encroach upon the topics which belong by right and usage to the readers of the main addresses and to the presidents of the various sections. With respect to the addresses, which it is customary to deliver on these occasions, medicine will be dealt with by one whose reputation is now world-wide—by our Osler—whose professional education was in great part received in this city, and who, I am happy to say, is still a Canadian. How he has been able to escape the alien law is a puzzle to many; but he has really only been borrowed for a time; he is merely passing through the United States in bond. We are only waiting until we can find a place large enough to hold him, when we will coax him back.

You will hear addresses in Surgery and Public Medicine, delivered by gentlemen who have devoted their lives to their special subjects.

A brief account of the history and the organization of the Association in its establishment of Colonial branches may not prove uninteresting. Canada has now seven branches, the Ottawa and Quebec branches having been formed within the last year. The formation of the Manitoba, Toronto, and Montreal branches was the immediate result of the visit to this country of Mr. Ernest Hart. In 1891, Mr. Hart, who has been editor of the *British Medical Journal* since 1867, passed through Canada, and addressed *en route* the members of the profession in Winnipeg, Toronto, and Montreal. In the course of a very happy speech made on this occasion by Mr. Hart he remarked that he looked forward to the time when the Canadian membership would be large enough to invite the Association to hold a meeting in Canada; and he hoped that the first meeting held outside the limits of the British Isles might be held in this country. Little did we think at the time that Mr. Hart's hopes would be so quickly realized.

One of the secrets of success of the British Medical Association is that it makes no distinction in the treatment of its members. Colonial members have all the privileges of the British members, and are always warmly welcomed at the headquarters in the Strand, and at the annual meetings. The Association has a large reserve fund of £40,000 sterling, which is the joint property of the members, to be used for public and professional purposes, and any suitable applications for grants for medical research, whether from British or Colonial members, always receive attention.

A gentleman to whom the Association is greatly indebted is Mr. Francis Fowke, who was appointed secretary and general manager in 1872. At that

time the Association was in rather a precarious condition financially, owing to its deficient organization; but shortly after Mr. Fowke took up the reins of office matters were found to improve steadily. Imagine the mighty power of the collective action of 17,000 earnest men pitted against false dogmas and ever battling for the truth! It is not, however, by the greatness of numbers that the Association will be judged—it is by the diversity and quality of results.

As it may be presumed that to the majority of those present here to-day Canada is almost an unknown country, I have thought that among one or two other subjects a few remarks on the atmospheric conditions and health-resorts of the Dominion would not be without interest.

The best way to understand the atmospheric conditions of a country is first to understand its physical features. The physical conditions of Canada are very remarkable. Broadly speaking, the country is separable by climatic and physical conditions into three great regions—the Eastern, Central, and Western regions, which approximately run north and south in the general trend of the continent. The Eastern region, which includes the older provinces of the Dominion—Ontario, Quebec, Nova Scotia, New Brunswick, and Prince Edward Island, besides the great fur territory stretching far to the east and northeast of James' Bay, extends from the Atlantic to Lake Superior and the chain of Great Lakes running in a northerly direction from Lake Superior to the Arctic Ocean. Between this great chain of lakes and the eastern base of the Rocky Mountains is the immense interior continental plain which constitutes the Central region of Canada, its southern part consisting of open prairie, its northern part of forest lands. The third part of the division, the Western region, is naturally well defined, consisting of the wide and wild mountainous border of the continent on the Pacific side—the Rocky, Selkirk, and Gold Ranges, which form the great Cordilleran belt, whose average width in Canada is 400 miles.

Eastern Canada is remarkable for its immense number of lakes, large and small, and for its irregular and winding rivers with numerous rapids and falls. Between the Laurentian Plateau on the north and the Appalachian mountain system on the south lies the great valley of the River St. Lawrence. The basin of this majestic river covers 530,000 square miles, of which 460,000 are in Canada. Above the city of Quebec the base of the Laurentian highlands and the ridges of the Appalachian system diverge, and the mighty river flows through an extensive low country of notable fertility in the earlier days of the great granary of Canada.

Included in the Eastern region is one of the most remarkable geographic features of Canada—the great fresh-water lakes or inland seas, Superior, Huron, Erie, and Ontario, which form the perennial reservoirs of the St. Lawrence. Together with Lake Michigan, which is wholly in the United States, they have an aggregate area of 94,750 square miles, an area larger than that of Great Britain. They stand at four distinct levels above the sea—Ontario, 247 feet; Erie, 573; Huron, 581, and Superior, 602. The Niagara Falls, the greatest and most impressive of the natural wonders of our continent, are the direct result of the great height of Lake Erie above Lake Ontario, the river connecting the lakes being only a few miles long. Besides the St. Lawrence, Eastern Canada has several other great rivers, notably the Ottawa, which has a course of 1800 miles and a basin of nearly 1,000,000 square miles, the St. Maurice, the Saguenay, and the St. John, the glory of New Brunswick, which, together with the Atlantic Slope, has a basin of 50,214 square miles. The Central and Western regions also have their abundant share of large and small lakes and great rivers, an account of which would fill reams of paper. It should be noted that the Canadian rivers and lakes collectively cover an area of 130,000 square miles and contain one-half the fresh water on the globe.

I draw special attention to this series of vast lakes and rivers because it exerts an immense and beneficent influence on the climate of Canada. It preserves the mean temperature while the land experiences the extremes. In summer the water is cooler and in winter warmer than the land conditions, which tend to modify the differences and to favor uniformity of climate. The southern boundary stretches over fully 4000 miles, along which line we find that Southern Ontario has the latitude of Central Italy, Nova Scotia that of Northern Italy, Manitoba and Vancouver that of Central Germany. Speaking generally, the Canadian summer may be stated at 60° to 70° F.

From its vast and varied extent, Canada may be said to be the possessor of several climates. Taking Solly's classification as to position, we have in Canada all the three land climates, the low, the medium, and the high. The first has an elevation up to 2500 feet, the second up to 4500, and the third from 4500 upwards. As to temperature and humidity, Canada comes under the category of "cold, moderate, and dry."

In the eastern region of the Dominion there are at least two localities which have been proved to possess many of the qualities which constitute a climate for convalescents from fevers and other depressing diseases, and also consumption in the incipient stage:

the Province of Quebec among the Laurentians, north of this city, of which the village of Ste. Agathe is the center; the other the Muskoka district in Ontario.

The first has been called the Adirondacks of Canada, having many of the features, physical and climatic, of that now celebrated plateau, situated in the northeastern part of the State of New York, and stretching from the Mohawk Valley in the south 150 miles north, almost to the frontier line. The average elevation of the two regions is about the same, being from 1600 to 1800 feet. The immense pine forests, together with the moderate temperature, constitute the chief characteristics of the Canadian district, from the medical point of view. No very systematic meteorologic observations have yet been taken of the Ste. Agathe region, but the indications will probably prove to be very similar to those of the American resort. It is in contemplation to erect a sanatorium on Trembling Mountain, overlooking the village of Ste. Agathe, which will doubtless in time rival the Adirondack Cottage Sanatorium near Saranac Lake Village, which has proved such a marked success under the able management of Dr. E. L. Trudeau. The elevation of the sanatorium will be 2500 feet, thus having an altitude of nearly 700 feet greater than the establishment at Saranac. It is the intention of the Quebec Government to set apart a sufficient portion of the Crown Lands to form a natural park in that part of the Province. It will be called the Trembling Mountain Park, and will cover an area of 100,000 acres of land, in which are several beautiful lakes. Within the boundaries of this park the sanatorium will be constructed.

One hundred miles north of Toronto, in the Highlands of Ontario, is the Muskoka Lake region, an area of about 10,000 square miles, perhaps the most picturesque portion of the whole Province. Within this district, which has a mean altitude above the sea of about 800 feet (200 feet above Lake Huron), there are nearly a thousand lakes and ponds, connected by innumerable streams. The chief lakes are Muskoka, Rosseau, and Joseph. These contain about 400 islands. It is a region abounding in pine forests; the climate is dry, and the air pure and invigorating.

In the Central Region of Canada, that section of the Northwest Territories known as Southern Alberta—the home of the cowboy—has much to recommend it as a health-resort. This strip of prairie and hill country is bounded on the north by the Canadian Pacific Railway, and on the south by the International boundary line. Patients can live there all the year round, and with the exception of an occasional snowstorm, which may cover the prairie to

a varying depth, nothing need interfere with their practically living in the saddle. The so-called Chinook wind has a remarkable influence over all this western section of Canada. It is a warm wind which blows with varying intensity from west to southwest. When the real Chinook blows the temperature often rises in a few hours from 30° below to 40° above zero. The snow, which in the morning may have been a foot deep, disappears, and before night everything is dripping. But in the space of a single day all the water is lapped up by the thirsty wind, and the prairie is so dry that a horse's hoof hardly makes an impression. It is well known that delicate lads sent from the British Isles to this section of the Northwest to work on the cattle ranches become in a year or two healthy and vigorous men, and are scarcely recognized on their return.

I think it can be satisfactorily proved that Canada is expressly fitted to develop a hardy race capable of great endurance. The races of the British Isles and the French race have certainly not degenerated here. Hingston proved this conclusively some years ago by observations made upon the medical students attending the various schools in this city. He found that the lumbar strength of the British-Canadian of the third generation exceeded by twenty pounds that of the recently arrived English and Scotch students. But the French-Canadian of the tenth generation did better than all by nearly thirty pounds. Not only has the French-Canadian increased in strength, but also in height and weight over the original Normandy stock.

Has the intellectual improvement in our people kept pace with the physical? We are a modest people, but I think we can say with truth that it has. We have a very respectable literature of our own, but the best intellect of the country is as yet absorbed in the practical affairs of life, and has too seldom found expression in art and literature.

We have in Canada several mineral springs of undoubted therapeutic value, and they are pretty generally distributed all over the Dominion, although differing materially in temperature and composition. The best known Canadian spas are the Caledonia, the St. Leon, and the Plantagenet Springs, in the Province of Quebec, and the Banff Springs in Alberta. Other springs in the Province of Quebec are the Abenakis and the Caxton. Besides these there are three or four artesian wells or springs. Of these the chief are the Laurentian Spring in the east end of this city (a mild alkaline water with sodium bicarbonate as its predominating ingredient), and the Radnor, a well of considerable repute situated in the County of Champlain. This was discovered a very few years ago when boring for water to supply

the workpeople engaged in the well known Radnor Forges. It has been likened to the German Seltzer, many of the properties being alike. It bids fair to become a rival in time of the celebrated Apollinaris water, to which it is preferred by many. The well is over 400 feet in depth. In the Province of Ontario the chief springs are the Winchester and the Preston, and those in the town of St. Catherines, near Niagara Falls. The best known and the most popular are the Caledonia Springs, situated on the line of the Canadian Pacific Railway, about midway between Montreal and Ottawa, and about nine miles from the Ottawa River.

The general question of medical education is one of great importance and of unceasing interest, nor is this interest confined to the profession; it is becoming universal. The needs of medical education are fortunately being more fully realized by those who, on account of their wealth and influence are in a position to render that substantial assistance which is so requisite. The time was when every medical school was a purely proprietary concern "run" for the money that was in it. We feel in Canada, and I think I can speak for the profession in the neighboring republic, that this day is past, that high-minded philanthropists like Lord Mount Royal, the late John Henry Molson, the McDonalds, the Drakes, and others with us, and the Johns Hopkins, the Stanfords, the Vanderbilts, the Rockefellers, the Miss Garretts, and others with them are beginning to realize that unendowed instruction in medicine must lead to imperfect results, and that private endowment, in the absence of State aid, has become an absolute necessity to a proper medical training.

Something of this kind has been recently attempted in the University of McGill. By a special arrangement with the Faculty of Arts it is now possible for students to obtain the degree of B.A. along with M.D., C.M., after only six years of study. It has been decided to allow the primary subjects (anatomy, physiology, and chemistry) in medicine to count as subjects of the third and fourth year in arts. It follows, then, that at the end of four-years' study a student may obtain his B.A. degree and have two years of his medical course completed. The last two years of study are, of course, devoted to the third- and fourth-year subjects in medicine. A certificate of Licentiate in Arts will be given along with the professional degree in medicine to those who previous to entrance upon their professional studies proper have completed two years in the Faculty of Arts, and have fully passed the prescribed examinations therein. By this plan also during the first two years of the arts course, the medical student practically completes his studies in physics, chemistry, botany, and ele-

mentary psychology. This scheme is still in the experimental stage, but there is every reason to believe that it will result satisfactorily. What deters so many from taking a full course in arts or science before entering medicine is the length of time consumed before the doctorate degree is reached, although I hope the time is not far distant when every graduate in medicine in Canada shall of necessity be also a graduate in arts or science.

I might state that the standard for the ordinary matriculation examination for entrance to medicine exacted by all universities and licensing boards in this country is, with one or two exceptions, very high. I doubt if the requirements in this way of the Medical Council of Great Britain are any higher.

Time will not permit of my discussing the subject of medical legislation in Canada at any length; and besides you will find it very fully treated in the excellent official guide or souvenir prepared for you by the Executive Committee.¹ In addition I might explain, however, that when the British-American provinces became confederated in 1867, under the British North America Act, the governance of educational matters was taken away from the Federal authorities and handed over to the provinces, each to look after them in its own way. In consequence we have since had a curious complexity of medical legislation, there being practically no uniformity among the provinces in regard to standard of study or qualification for practice. Each province has its own medical board or medical council, as the case may be, which has the power to grant license to practice, either after examination or on simply presenting the diploma of certain recognized universities. In the Provinces of Ontario and British Columbia, an examination is exacted; in the others the license is given under certain restrictions on presentation of the degree, although in the Maritime Provinces an examining board is now about to be established. In this way, as can readily be seen, a Chinese wall is built round each province, and the frontier is carefully guarded so that it is unsafe for a medical man to pass from one to the other unarmed with a license, because of the risk of fine or even imprisonment. Such a condition of affairs is hardly credible, and probably exists nowhere else to the same extent. What is the remedy? Two remedies have been suggested—either the establishment of a central examining board in each province with a uniform standard of matriculation and a uniformly high standard of curriculum which shall in time lead up to a general scheme of reciprocity; or, secondly, a Dominion Examining Board. The first scheme is at present under serious consideration, although there are many difficulties in the way of its accomplishment, none

of which is insuperable, however, providing a spirit of conciliation prevails. The second alternative (a Dominion Examining Board) would in many respects be more desirable, because not only could the licensee practise in any part of the Dominion, but he could register in Great Britain, and thus receive recognition all over the empire.

In conclusion, allow me to express the hope that the arrangements made by the Executive Committee for the entertainment of our guests may meet with appreciation and approval, and that the memories of the brief sojourn here may be all that is bright and happy.

BRITISH MEDICINE IN GREATER BRITAIN.¹

BY WILLIAM OSLER, M.D.,

OF BALTIMORE;

PROFESSOR OF MEDICINE IN JOHNS HOPKINS UNIVERSITY.

To trace successfully the evolution of any one of the learned professions would require the hand of a master—of one who, like Darwin, combined the capacity for patient observation with philosophic vision. In the case of medicine the difficulties are enormously increased by the extraordinary development which belongs to the history of the present century. The rate of progress has been too rapid for us to appreciate, and we stand bewildered, as it were, in a state of intellectual giddiness when we attempt to obtain a broad, comprehensive view of the subject. In a safer "middle flight" I propose to dwell on certain of the factors which have molded the profession in English-speaking lands beyond the narrow seas—of British medicine in Greater Britain.

Evolution advances by such slow and imperceptible degrees that to those who are part of it the finger of time scarcely seems to move. Even the great epochs are seldom apparent to the participants. During the last century neither the colonists nor the mother country appreciated the thrilling interest of the long-fought duel for the possession of this continent. The acts and scenes of the drama, to them detached, isolated, and independent, now glide like dissolving views into each other, and in the vitascope of history we can see the true sequence of events. That we may meet here to-day, Britons on British soil, in a French province, is one of the far-off results of that struggle. This was but a prelude to the other great event of the Eighteenth Century: the revolt of the colonies and the founding of a second great English-speaking nation—in the words of Bishop Berkeley's prophecy, "Time's noblest offspring."

Surely a unique spectacle that a century later de-

¹ Abstract of the Address in Medicine delivered at the Sixty-fifth Annual Meeting of the British Medical Association, Montreal, August 31 to September 3, 1897.

scendants of the actors of these two great dramas should meet in an English city in New France! Here, the American may forget Yorktown in Louis-berg, the Englishman Bunker Hill in Quebec, and the Frenchman both Louisberg and Quebec in Chateauguay; while we Canadians, English and French, in a forgiving spirit, overlooking your unseemly quarrels, are only too happy to welcome you to our country—this land on which and for which you have so often fought.

We English are the modern Greeks, and we alone have colonized as they did, as free peoples. There have been other great colonial empires—Phenician, Roman, Spanish, Dutch, and French—but in civil liberty and intellectual freedom *Magna Græcia* and Greater Britain stand alone. The parallel so often drawn between them is of particular interest with reference to similarity between the Greek settlements in Sicily and the English plantations on the Atlantic coast. Indeed, Freeman says: "I can never think of America without something suggesting Sicily, or of Sicily without something suggesting America." I wish to use the parallel only to emphasize two points, one of difference and one of resemblance. The Greek colonist took Greece with him. Hellas had no geographic bounds. "Massilla and Olbia were cities of Hellas in as full a sense as Athens or Sparta." The emigrant Britons likewise changed their sky, not their character, in crossing the great sea; yet the home-stayers had never the same feeling toward the plantations as the Greeks had toward the colonial cities of *Magna Græcia*. The assumption of gracious superiority which, unless carefully cloaked, smacks just a little of our national arrogance, is apt to jar on sensitive colonial nerves. With the expansion of the Empire and the supplanting of a national by an imperial spirit, this will become impossible.

It would carry me too far afield to discuss the differences between the native Briton and his children scattered so widely up and down the earth. In Canada, South Africa, Australia, and New Zealand types of the Anglo-Saxon race are developing which will differ as much from each other, and from the English, as the American does to-day from the original stock; but amid these differences can everywhere be seen those racial qualities which have made us what we are—"courage, national integrity, steady good sense, and energy in work."

Could some one with full knowledge patiently analyze the characteristics of British medicine he would find certain national traits sufficiently distinct for recognition. Three centuries cannot accomplish very much (and that period has only just passed since the revival of medicine in England), but the local

conditions of isolation, which have been singularly favorable to the development of special peculiarities in the national character, have not been without effect in the medical profession.

Above the fireplace in Sir Henry Acland's study are three paneled portraits of Linacre, Sydenham, and Harvey; the scroll upon them reads *Littera, Praxis, Scientia*. To this great triumvirate—as to the fountain-heads, we may trace the streams of inspiration which have made British medicine what it is to-day.

Linacre, the type of the literary physician, must ever hold a unique place in the annals of our profession. To him was due in great measure the revival of Greek thought in the Sixteenth Century in England, and in the last Harveian oration Dr. Payne pointed out his importance as a forerunner of Harvey. He made Greek methods available; through him the art of Hippocrates and the science of Galen became once more the subject of careful, first-hand study. Linacre, as Dr. Payne remarks, "was possessed from his youth till his death by the enthusiasm of learning. He was an idealist devoted to objects which the world thought of little use." Pains-taking, accurate, critical, hypercritical perhaps, he remains to-day the chief literary representative of British medicine.

While in critical scholarship and in accurate historical studies British medicine must take a second place, the influence of Linacre, exerted through the Royal College of Physicians and the old universities, has given to the humanities an important part in education, so that they have molded a larger section of the profession than in any other country. A physician may possess the science of Harvey and the art of Sydenham, and yet there may be lacking in him those finer qualities of heart and head which count for so much in life. Medicine is seen at its best in men whose faculties have had the highest and most harmonious culture. The Lathams, the Watsons, the Pagets, the Jenners, and the Gairdners have influenced the profession less by their special work than by exemplifying those graces of life and refinements of heart which make up character. And the men of this stamp in Greater Britain have left the most enduring mark—Beaumont, Bovell, and Hodder in Toronto; Holmes, Campbell, and Howard in this city; the Warrens, the Jacksons, the Bigelows, the Bowditches, and the Shattucks in Boston; Bard, Hossack, Francis, Clark, and Flint of New York; Morgan, Shippen, Redman, Rush, Coxe, the elder Wood, the elder Pepper, and the elder Mitchell of Philadelphia—Brahmins all, in the language of the greatest Brahmin among them, Oliver Wendell Holmes—these and men like unto them have been

the heaven which has raised our profession above the dead level of a business.

In the pictures referred to, Sydenham is placed between Linacre and Harvey; but science preceded practice, and Harvey's great Lumleian lectures were delivered before Sydenham was born. Linacre has been well called, by Payne, Harvey's intellectual grandfather. Harvey returned to Greek methods, and became the founder of modern experimental physiology, and the great glory of British scientific medicine. The demonstration of the circulation of the blood remains in every detail a model research. Harvey was a practitioner and a hospital physician. It is remarkable that a large proportion of all the physiologic work of Great Britain has been done by men who have become successful hospital physicians or surgeons, the better men preferring an active life in practice to a secluded laboratory career.

Thucydides it was who said of the Greeks that they possessed "the power of thinking before they acted, and of acting, too." The same is true in a high degree of the English race. To know just what has to be done, then to do it, comprises the whole philosophy of practical life. Sydenham—*Anglie lumen*, as he has been well called, is the model practical physician of modern times. He laid down the fundamental proposition, and acted upon it, that "all diseases should be described as objects of natural history." To do him justice we must remember, as Dr. John Brown says, "in the midst of what was a mass of errors and prejudices, of theories actively mischievous, he was placed, at a time when the mania of hypothesis was at its height, and when the practical part of his art was overrun and stultified by vile and silly nostrums." Sydenham led us back to Hippocrates; I would that we could be led oftener to Sydenham! Sydenham, not Linacre or Harvey, is the model British physician in whom were concentrated all those practical instincts upon which we lay such stress in the Anglo-Saxon character.

The Greek faculty which we possess of thinking and acting has enabled us, in spite of many disadvantages, to take the lion's share in the great practical advances of medicine. Three among the greatest scientific movements of the century have come from Germany and France. Bichât, Lænnec, and Louis laid the foundation of modern clinical medicine; Virchow and his pupils of scientific pathology, while Pasteur and Koch have revolutionized the study of the causes of disease; and yet, the modern history of the art of medicine could almost be written in its fulness from the records of the Anglo-Saxon race. We can claim almost every practical advance of the very first rank—vaccination, anesthesia, preventive medicine, and antiseptic surgery, the "captain jewels

in the coronet" of the profession, beside which can be placed no others of equal luster.

But there are signs of a great change. The old universities and the colleges, once the chief offenders, have been emancipated, and remain no longer, as Gibbon found them, steeped in port and prejudice. The value of authority *per se*, has lessened enormously, and we of Greater Britain have perhaps suffered as the pendulum has swung to the other extreme. Practice loves authority, as announced in "the general and perpetual voice of men." Science must ever hold that a judicious distrust and wise skepticism are the sinews of the understanding. And yet the very foundations of belief in almost everything relative to our art rest upon authority. The practitioner cannot always be the judge; the responsibility must often rest with the teachers and investigators, who can only learn in the lesson of history the terrible significance of the word.

Turning now to the main question of the development of this British medicine in Greater Britain, I can only indicate a few points of importance, and I must confine my remarks chiefly to the American part of Greater Britain. We may recognize three distinct periods corresponding to three distinct waves of influence, the first from the early immigration to about 1820, the second from about 1820 to 1860, and the third from about 1860 to the present time.

The colonial settlements were contemporaneous with the revival of medicine in England. Fellow-students of Harvey at Cambridge might have sailed in the "Mayflower" and the "Arbella." The more carefully planned expeditions usually enlisted the services of a well-trained physician, and the early records, particularly of the New England colonies, contain many interesting references to these college-bred men. Giles Firman, who settled in Boston in 1632, a Cambridge man, seems to have been the first to give instruction in medicine in the New World. The parsons of that day had often a smattering of physic, and illustrated what Cotton Mather called an "angelical conjunction." He says: "Ever since the days of Luke, the Evangelist, skill in *Physick* has been frequently professed and practised by Persons whose more declared Business was the study of Divinity." Firman himself, finding physic "but a meane help," took orders. These English physicians in the New England colonies were scholarly, able men. Roger Chillingworth, in Hawthorne's "Scarlet Letter," has depicted them in a sketch of his own life: "Made up of earnest, studious, thoughtful, quiet years, bestowed faithfully for the increase of knowledge, faithfully, too, for the advancement of human welfare—men, thoughtful for others, caring little for themselves, kind, just, true, and of constant

if not warm affections"—a singularly truthful picture of the old colonial physician.

Until the establishment of medical schools—University of Pennsylvania, 1763, King's College (afterward Columbia), 1767, Harvard, 1782—the supply of physicians for the colonies came from Great Britain, supplemented by men trained under the old apprentice system, and of colonists who went to Edinburgh, Leyden, and London for their medical education. This latter group had a most powerful effect in molding professional life in the pre-revolutionary period. They were men who had enjoyed not alone the instruction, but often the intimate friendship of the great English and European physicians. Morgan, Rush, Shippen, Bard, Wistar, Hossack, and others received an education comprising all that was best in the period, and acquired the added culture which can only come from travel and wide acquaintance with the world. Morgan, the founder of the medical school of the University of Pennsylvania, was away seven years, and before returning had taken his seat as a corresponding member of the French Academy of Surgery, besides having been elected a Fellow of the Royal Society. The War of Independence interrupted temporarily the stream of students, but not the friendship which existed between Cullen and Fothergill and their old pupils in America. The correspondence of these two warm friends of the colonies testifies to the strong professional intimacy which existed at the time between the leaders of the profession in the Old and New Worlds.

But neither Boerhaave, Cullen, nor Fothergill stamped colonial medicine as did the great Scotchman, John Hunter. Long, weary centuries separated Harvey from Galen; not a century elapsed from the death of the great physiologist to the advent of the man in whose phenomenal personality may be seen all the distinctive traits of modern medicine, and the range of whose mighty intellect has had few, if any, equals since Aristotle. Hunter's influence on the profession of this continent, so deep and enduring, was exerted in three ways. In the first place, his career as an army surgeon, and his writings on subjects of special interest to military men, carried his work and ways into innumerable campaigns in the long French wars and in the War of Independence. Hunter's works were reprinted in America as early as 1791 and 1793. In the second place, Hunter had a number of most distinguished students from the colonies, among whom were two who became teachers of wide reputation—William Shippen, the first professor of anatomy in the University of Pennsylvania, who lived with Hunter on terms of the greatest intimacy, and Philip Syng Physick, who was his house surgeon at St. George's Hospital, and his devoted

friend. But in a third and much more potent way the great master influenced the profession of this continent. Hunter was a naturalist to whom pathologic processes were only a small part of a stupendous whole, governed by law, but which could never be understood until the facts had been accumulated, tabulated, and systematized. He made all thinking physicians naturalists, and he lent a dignity to the study of organic life, and re-established a close union between medicine and the natural sciences. In the latter part of the last century and during the first thirty years of this, the successful practitioner was very often a naturalist. In Canada, many of our best naturalists have been physicians, and collections in this city testify to the industry of Holmes and McCullough.

Until about 1820, the English profession of this continent knew little else than British medicine. After this date, in the United States the ties of professional union with the old country became relaxed, owing in great part to the increase in the number of home schools, and in part to the development of American literature. To 1820, 114 native medical books of all kinds had been issued from the press, and 131 reprints and translations, the former English, the latter, few in number, and almost exclusively French (Billings).

Turning for a few minutes to the condition of the profession in Canada during this period, I regret that I cannot speak of the many interesting questions relating to the French colonies. With the earliest settlers, physicians had come, and among the Jesuits, in their devoted missions, there are records of *donnés* (laymen attached to the service), who were members of the profession. One of these, René Goupil, suffered martyrdom at the hands of the Iroquois.¹

Between the fall of Quebec in 1759, and 1820 the English population had increased by the settlement of Upper Canada, chiefly by United Empire loyalists from the United States, and after the War of 1812, by settlers from the old country. The physicians in the sparsely settled districts were either young men who sought their fortunes in the new colony or were army surgeons, who had remained after the Revolutionary War or the War of 1812. The military element gave for some years a very distinctive stamp to the profession. These surgeons were men of energy and ability, who had seen much service, and were accustomed to order, discipline, and regulations.

One picture on the canvas of those early days lingers in the memory, illustrating all the most attractive features of a race which has done much to make this country what it is to-day. Widmer was

¹ Parkman, "Jesuits in North America."

the type of the dignified old army surgeon, scrupulously punctilious, and in every detail regardful of the proprieties of life. "Tiger" Dunlop may be taken as the very incarnation of that restless, roving spirit which has driven the Scotch broadcast upon the world. After fighting with the Connaught Rangers in the War of 1812, campaigning in India, clearing the Sangur of tigers—hence his sobriquet "Tiger,"—lecturing on medical jurisprudence in Edinburgh, writing for *Blackwood*, editing the *British Press* and the *Telescope*, introducing "Beck's Medical Jurisprudence" to English readers, and figuring as director and promoter of various companies, this extraordinary character appears in the young colony as "Warden of the Black Forest" in the employ of the Canada Company. His life in the backwoods at Gairbraid, *Noctes Ambrosianæ Canadensis*, his famous "Twelve apostles" as he called his mahogany liquor-stand (each bottle a full quart), his active political life, his remarkable household, his many eccentricities—are they not all portrayed to the life in the recently issued "In the Days of the Canada Company?"

Turning now to the second period, we may remark in passing that the Nineteenth Century did not open very auspiciously for British medicine. Hunter had left no successor, and powerful as had been his influence, it was too weak to stem the tide of abstract speculation, with which Cullen, Brown, and others flooded the profession.

The awakening came in France, and such an awakening! It can be compared with nothing but the Renaissance in the Sixteenth and Seventeenth Centuries, which gave us Vesalius and Harvey. "Citizens" Bichât and Broussais led the way, but Lænnec really created clinical medicine as we know it to-day. The revival of medicine in Great Britain was directly due to the French. Bright and Addison, Graves and Stokes, Forbes and Marshall Hall, Latham and Bennett were profoundly affected by the new movement. In the United States, Anglican influence did not wane until after 1820. Translations of the works of Bichât appeared as early as 1802, and there were reprints in subsequent years, but it was not until 1823 that the first translation (a reprint of Forbes' edition) of Lænnec was issued. Broussais' works became very popular in translations after 1830, and in the journals from this time on the change of allegiance became very evident. But men rather than books diverted the trend of professional thought. After 1825 American students no longer went to Edinburgh and London, but to Paris, and we can say that between 1830 and 1860 every teacher and writer of note passed under the Gallic yoke. The translations of Louis' works and the extraordinary success of his American pupils, a band of

the ablest young men the country had ever seen, added force to the movement.

In Canada, the period from 1820 to 1860 saw the establishment of the English universities and medical schools. In Montreal the agencies at work were wholly Scotch. The McGill Medical School was organized by Scotchmen, and from its inception has followed closely Edinburgh methods. The Paris influence, less personal, was exerted chiefly through English and Scotch channels. The Upper Canada schools were organized by men with English affiliations, and the traditions of Guys, St. Bartholomew, St. Thomas, St. George, and of the London Hospital, rather than those of Edinburgh, have prevailed in Toronto and Kingston.

The third period dates from about 1860 when the influence of German medicine began to be felt. Teutonic medicine began to be manifested as a vitalizing power chiefly through the energy of Virchow. After the translation of the "Cellular Pathology" by Chance (1860) the way lay clear and open to every young student who desired inspiration. There had been great men in Berlin before Virchow, but he made the town on the Spree a Mecca for the faithful of all lands. From this period we can date the rise of German influence on the profession of this continent. It came partly through the study of pathologic histology, under the stimulus given by Virchow, and partly through the development of the specialties, particularly diseases of the eye, of the skin, and of the larynx.

In certain aspects the Australasian Settlements present the most interesting problems of Greater Britain. More homogeneous, thoroughly British, isolated, distant, they must work out their destiny with a less stringent environment than, for example, surrounds the English in Canada. The traditions are more uniform and of whatever character have filtered through British channels. The professional population of native-trained men is as yet small, and the proportion of graduates and licentiates from the English, Scotch, and Irish colleges and boards guarantees a dominance of Old-Country ideas. What the maturity will show cannot be predicted, but the vigorous infancy is full of promise.

Of India, of "Vishnu-land," what can one say in a few minutes? Three thoughts at once claim recognition. Here in the dim dawn of history, with the great Aryan people, was the intellectual cradle of the world. To the Hindus we owe a debt which we can at any rate acknowledge; and even in medicine many of our traditions and practices may be traced to them.

In estimating the progress of medicine in the countries comprising Greater Britain, the future

rather than the present should be in our minds. The awakening of the profession in the United States to a consciousness of its responsibilities and opportunities has caused unparalleled changes, which have given an impetus to medical education and to higher lines of medical work, which has already borne a rich harvest. Within two hundred years who can say where the intellectual center of the Anglo-Saxon race will be? The mother country herself has only become an intellectual nation of the first rank within a period altogether too short to justify a prediction that she has reached the zenith. She will probably reverse the history of Hellas, in which the mental superiority was at first with the colonies. At the end of the next century, ardent Old-World students may come to this side "as o'er a brook," seeking inspiration from great masters, perhaps in this very city; or the current may turn toward the schools of the great nations of the South.

Meanwhile, to the throbbing vitality of modern medicine the two great meetings held this month, in lands so widely distant, bear eloquent testimony. Free, cosmopolitan, no longer hampered by the dogmas of schools, we may feel a just pride in a profession almost totally emancipated from the bondage of error and prejudice. Distinctions of race, nationality, color, and creed are unknown within the portals of the temple of Æsculapius. Some Son of Beor, touched with prophetic vision, piercing the clouds which now veil the eternal sunshine of the mountain-top—some spectator of all time and all existence (to use Plato's expression)—might see in this gathering of men of one blood and one tongue a gleam of hope for the future, of hope at least that the great race so dominant on the earth to-day may progress in the bonds of peace—a faint glimmer perhaps of the larger hope of humanity, of the day when "the common sense of most shall hold a fretful world in awe."

THE SURGEON OF OLD IN WAR.¹

By W. MITCHELL BANKS, M.D.,
OF LIVERPOOL, ENGLAND;

FELLOW AND MEMBER OF COUNCIL OF THE ROYAL COLLEGE OF
SURGEONS OF ENGLAND; SURGEON TO THE LIVERPOOL ROYAL
INFIRMARY; EMERITUS PROFESSOR OF ANATOMY,
UNIVERSITY COLLEGE, LIVERPOOL.

I AM indeed greatly honored by having to deliver to you to-day an Address in Surgery. Fortunately for me the title is a wide one, and I shall take advantage of that fact to diverge from the strict consideration of surgical disease, and shall offer you instead a brief sketch of some of the most notable work done of old by a body of members of our pro-

fession who have never received their due reward—those, namely, who have devoted their lives to the succor of the sick and wounded in war.

Military Surgeons in the Roman Army.—Twelve months ago my friend, Dr. Barnes of Carlisle, ex-President of this Association, made me acquainted with a remarkable paper by the late Sir James Simpson, entitled "Was the Roman Army Provided with Medical Officers?"—a paper exhibiting such profound learning, so charmingly written, and so little known that I need not make any apology for acquainting you with some of its chief points of interest.

The most careful investigations have failed to make out from their writings whether the Romans regularly appointed physicians and surgeons to their armies or not, although nearly every other question relating to their military organization has been treated, sometimes very fully. Curiously enough, what little information we possess on the subject comes mainly from mortuary or from votive tablets.

The First Tungrian Cohort is known to have been present at the battle of the *Mons Grampius*, and to have served at Castlecary, at Cramond near Edinburgh, in Cumberland, and at Housesteads. The tablet is highly ornamented, and antiquarians hold that a rabbit and round bucklers carved in the upper part, which are emblems of Spain, show that the young military doctor was probably a native of that country. From various works treating of Roman inscriptions Simpson was enabled to find that four more tablets, in which surgeons of cohorts are mentioned, exist. They were found at Rome.

Ambroise Paré.—Hundreds of years went past before there came upon the scene any military surgeon of note, but when he did appear he was a man of transcendent merit—the illustrious Ambroise Paré. From 1517 to 1590, for seventy-three years, he lived an incessantly active life, the contemporary of Vesalius, the immediate predecessor of Harvey. We have only time to glance at the soldier-surgeon side of Paré's life. For over thirty years he followed the wars under four kings of France—Henry the Second, Francis the Second, Charles the Ninth, and Henry the Third, with intervals of a few years at home in Paris. Perpignan, Metz, Verdun, Rheims, Hesdin (where he was taken prisoner and had to write to his wife for his ransom), St. Quintin, La Fère, Amiens, the taking of Rouen, Dreux, Moncontour—these are but some of the bloody battles and sieges at which he was present. Through them all his humanity, his love of his profession, his independent character, and his jovial, frank disposition carried him safe, and made for the son of the poor country joiner warm friends among the greatest and noblest warriors of France.

¹ Abstract of an Address delivered at the Sixty-fifth Annual Meeting of the British Medical Association, Montreal, August 31 to September 3, 1897.

Amid all the splendid work, both anatomic and surgical, which Paré did the application of the principle of the ligature to bleeding arteries is of course that with which his name will be forever associated. In this day of grace it is impossible for us to imagine the horrors which awaited a wretched man as soon as his limb was cut off and the process of stopping the bleeding began. Think of the raw and exquisitely sensitive stump exposed to the red hot cautery or plunged into boiling pitch! For this frightful treatment Paré substituted the ligature, which in our own day, employed in the form of an aseptic animal material which the tissues quietly absorb, has practically reached the pitch of perfection. In his time, too, there was a fixed belief that the danger from gunshot wounds arose from the poison of the gunpowder conveyed on the bullet. To destroy this poison the treatment was to pour into the wound boiling oil in which elderwood bark had been stewed. On one occasion, not having this infernal concoction at hand, Paré used a cold mixture of yolk of egg, oil of roses, and turpentine to his wounded soldiers. He passed a sleepless night from dread that this would injure those to whom it had been applied, and his delight next day was proportionately great when he found that they had had but little pain, while their wounds were free from inflammation and swelling. This was his panacea for wounds ever afterward. There are of course persons who wish to make out that he was not original in the matter of the ligature. He himself says this about it: "Taught me, as I interpret it, by the suggestion of some good Angel, for I neither learned it of my masters nor of any other man. And thus I wish all chirurgions to doe. For it is not in our Art, as it is in civil affaires, that prescription, law, or authority should prevail over right reason."

Interesting mention is then made of Robert Clowes, an English surgeon who saw no little fighting between the years 1560 and 1604. Another interesting character was Peter Lowe, a contemporary of Clowes, whose studies marked a distinct advance in the knowledge of gunshot wounds. "Some think that there is a venenosity in the powder and a burning in the bullet; which is false, for the things whereof the powder is ordinarily made, as brimstone, saltpeter, coales of divers sorts of trees, water, wine, and aquæ vitæ, have no venenosity in them; likewise there is no burning in the bullet, for if the bullet of lead being shot a great way should burn, through heat would be melted itself." Next in order of military surgeons came John Woodall, who wrote the first English work especially devoted to military and naval surgery. Following him came Richard Wiseman, who has been termed the "father of English surgery," and not without reason. Wise-

man believed in the need of giving stimulants to a man who was in the habit of taking them if that man was in a dire strait. Speaking of the "Dunkirkers at sea," he says: "I could scarce ever cure them without allowing them wine, and thereby their spirits were kept up, and I had the liberty to bleed them as I thought fit."

Baron Larrey.—Up till the time of the French Revolution it is clear that military surgeons were not men of much importance, and probably had very little influence, if any, in the conduct of campaigns. But in the latter part of the last century war was made on a scale which was never known before, and was made also with a rapidity and a precision quite unprecedented. Moreover, the science and art of surgery had been rescued from quackery, and surgeons in actual practice were able to be of great and real service to the wounded. As a result of the vast masses of men that were hurled against each other, the number of wounded after a big battle amounted to thousands, and civilization had so far advanced that it was imperative that immediate help should be given them, so that about this time the military surgeon really became an important officer in warfare, and began to have his rank and pay well defined, and his merits (up to a certain point) recognized.

In 1776, near the Pyrenees, was born Jean Dominique Larrey, the *Chirurgien-en-Chef de la Grande Armée*, the friend and body-surgeon of Napoleon, and the greatest military surgeon that ever lived. He studied at the medical school of Toulouse, and in 1792 joined the headquarters of the Republican Army of the Rhine under Custine. Now, the ambulances of these days were obliged to remain about a league from the army, and the wounded were only picked up after the fighting was done. General Custine was a man who moved his troops very rapidly, which made matters worse for the wounded. This greatly affected Larrey, who set to work and devised a new ambulance hung on springs, and combining great strength with lightness. Such carriages were termed *ambulances volantes*. They could keep up with the advance guard of the army with the speed of flying artillery, and they carried off the wounded almost as they fell. Larrey had early perceived the enormous advantage a wounded man got by having his fracture set or his bleeding stopped as rapidly as possible, and by getting a roof over his head before night set in. General Beauharnais, in a despatch to the Convention, made special mention of "Surgeon-Major Larrey and his comrades with flying ambulances, whose indefatigable care in the healing of the wounded has diminished those afflicting results to humanity which have generally been inseparable

from days of victory, and have essentially served the cause of humanity itself in preserving the brave defenders of our country." The staff of a flying ambulance was about 340 in number. For each division there were four heavy carriages and twelve light ones. Some had two and others four wheels, and they were furnished with mattresses. In Napoleon's Italian campaigns they came greatly to the fore, and the great man displayed a lively interest in them, reviewing them and causing them to maneuver before him just as if they were on a battle-field. After one of these inspections he said to Larrey: "Your work is one of the most happy conceptions of our age. It will suffice for your reputation."

When Napoleon undertook his Egyptian campaign Larrey proceeded to Toulon to organize the medical staff. So readily did professional men respond to the call made by him that he was soon able to reckon on 800 well-qualified surgeons, of whom many had served in the army of Italy, and these were in addition to the medical officers actually attached to the regiments. This, I think, shows the value that the king of commanders set upon the health of his troops, and the trouble and expense which he was prepared to face in order to maintain it—a great contrast to the miserable way of dealing with this subject which has too long been the fashion with our military rulers. Not long after the landing at Alexandria a certain General Figuières was severely wounded. By able treatment he recovered, and in gratitude for the preservation of his life he asked Napoleon to accept a valuable Damascus sword. "Yes," said the latter, "I accept it in order to make a present of it to the Surgeon-in-Chief, by whose exertions your life has been spared." Upon the sword was engraved the words "Aboukir" and "Larrey," and the surgeon had it till the fatal day of Waterloo, when the Prussians robbed him of it.

Following his adored master through victory and defeat, Larrey at last stood alone at night on the field of Waterloo, except for some medical officers and the wounded who lay groaning around them. Down upon them came a squadron of Prussian lancers. Expecting no quarter, he fired his pistols at them and galloped away. They shot his horse and sabered him as he lay on the ground. Leaving him apparently dead, they went off. But he recovered his senses, and tried to crawl by cross-roads into France. Again he was seized by another detachment of Prussian cavalry. They robbed him promptly of all he possessed, and took him before a superior officer, who ordered him to be shot. What a reward from a soldier to one whose life had been passed in succoring soldiers! About a quarter of an hour before the sentence was to be carried out, a surgeon-major

recognized Larrey. He had attended with deep interest a course of lectures which Larrey had delivered in Berlin six years previously. The prisoner was brought before Bulow, and finally presented to Blücher, whose son had been badly wounded in the Austrian campaign, and captured by the French, and who owed his life to Larrey's exertions.

Larrey's honorable and glorious life terminated in 1842. Napoleon, when he made his will at St. Helena, wrote in it: "I bequeath to the Surgeon-in-Chief of the French Army, Larrey, 100,000 francs. He is the most virtuous man I have ever known." From Napoleon's lips the words of free, spontaneous, ungrudging praise such as this rarely fell.

Pestilence More Deadly than the Sword.—In the middle of the last century, while surgery had distinctly improved, the gross neglect of the Government, and the pig-headed obstinacy of the generals was such that our unfortunate soldiers and sailors were hardly any better off than they were in the days of Paré. It has been maintained that Smollett, in the appalling picture of naval life as witnessed in the miserable expedition to Carthage which he drew in "Roderick Random," and which is known to have been the record of his own experience as a surgeon's mate, grossly exaggerated the evils thereof. I do not believe this. Look at the awful and unsuccessful expedition to Porto Bello in 1726, when nearly the whole of the crews of the ships were destroyed by fever three times over; where two admirals, ten captains, fifty lieutenants, and about three to four thousand inferior officers and men perished without striking a blow. Look at the taking of Havana in 1762. The Earl of Albemarle took with him in the fleet 11,000 soldiers. Between June and the middle of October, when Cuba was ours, we had lost 560 men by wounds, and 4708 by sickness. At the end of the Seven-Years' War, a statement was drawn up in the *Annual Register* for 1763 from which it appeared that in all the naval battles of that war there were but 1512 sailors and marines killed while 133,738 had died of diseases or were "missing." Look even at the end of last century, and consider the wretched and disgraceful Walcheren campaign. Never did our poor soldiers fight with more gallantry than in that campaign, only to perish beside Dutch ditches and canals from fever and ague and dysentery.

Military Courage.—As we have just seen, Baron Larrey's whole life shows that, while absolutely devoted to the work of his profession, he displayed a cool courage on the field of battle not less heroic than the more dazzling deeds of his fellow combatant officers. Not less does it mark the military surgeon of the present day. Have you ever heard of

Surgeon Thomson who, during the Crimean war, when the army marched off after the battle of the Alma, volunteered, with his servant, John McGrath, to remain behind on the open field with 500 terribly wounded Russians, and passed three awful days and nights—these two Englishmen alone—among foreign foes, some dead, some dying, and none able to raise a hand to help themselves? Have you ever heard of Assistant-Surgeon Wolseley, of the 20th Regiment, who, at the battle of Inkerman, had quietly established his field hospital in that awful place, the Sandbag Battery? When the 150 men, who were all that remained of its defenders, were forced to desert it, about 100 of them fell back in one direction, and in that they found, at thirty paces from them, a Russian battalion blocking their path. There was not a combatant officer left; so the assistant-surgeon took command. He had not even a sword with him, but, laying hold of a firelock with a fixed bayonet on it, he spoke a few words to the men within range of his voice, and told them that what they now had to fight for was not victory but life. Then he gave them the word of command: "Fix bayonets, charge, and keep up the hill." The soldiers answered him with a burst of hurrahs, sprang forward to the charge, and the next instant were tearing through the thickest of the Russians. One-half of these reached the other side alive. Have you ever heard of Surgeon Landon, who was shot through the spine while attending the wounded on Majuba Hill? His legs were paralyzed, but he caused himself to be propped up, and continued his merciful work till his strength ebbed away. When unable to do more he quietly said: "I am dying; do what you can for the wounded." Have you ever heard of Surgeon-Captain Whitchurch, who gained the Victoria Cross at the beleaguering of Chitral for the most determined courage in endeavoring to save the life of Major Baird? Yes, you have for last year at Carlisle you gave him the gold medal of the Association, the highest honor which our Association can give to its members. There died the other day a certain Surgeon-General Reade, C.B., V.C. During the siege of Delhi, while attending to the wounded at the end of one of the streets of the city, a party of rebels advanced from the direction of the bank, and having established themselves in the houses in the street commenced firing from the roofs. The wounded were thus in very great danger, and would have fallen into the hands of the enemy had not Surgeon Reade drawn his sword and, calling upon a few soldiers who were near to follow, succeeded under a very heavy fire in dislodging the rebels from their position. Surgeon Reade's party consisted of about ten in all, of whom two were killed and five or six wounded. Ladies and

gentlemen, Surgeon Reade was a Canadian, and the son of a colonel of the Canadian Militia. Of the 118 wearers of the Victoria Cross 14 are surgeons, nearly 12 per cent. of the whole number. They stand in the proportion of $9\frac{1}{2}$ per cent. of all the officers of the army, so at all events they have contributed not less than their fair share of the deeds of valor which alone can win that glorious distinction.

The Army Medical Service To-day.—I have diverged from the beaten track common to the givers of addresses such as this to tell you what splendid men have been the military and naval surgeons of old, who not merely did their duty nobly and courageously as such, but who have in their day enormously contributed to the advance of the art of surgery. I have done it with a purpose; with the hope of attracting more strongly than ever the sympathy and help of this great Association to their military brethren in a critical juncture of their history. To-day Her Majesty's Government cannot induce candidates to come forward for the medical service of the Queen's army. And why? Because it has persistently treated the Army Medical Department meanly and shabbily. To-day the Government of India can secure the services of the pick of our newly fledged doctors for its army. And why? Because it has always treated the Indian Medical Service liberally and generously. I am not going to enter into the reasons for this; I merely desire to emphasize one point, namely, that money is not at the bottom of this difficulty.

CLINICAL MEMORANDA.

A CASE OF NYMPHOMANIA.¹

BY JOHN O. POLAK, M.D.,
OF BROOKLYN, N. Y.

LIZZIE B., aged twenty-nine, single, of German parentage, was seen by the writer in consultation with Dr. Wm. Boes, October 1, 1896. The following history was elicited: Her mother has suffered from melancholia since her menopause, which followed closely upon the birth of her last child. Her father and brother are in perfect health. The patient had the diseases common to childhood, which were not followed by complications. She first menstruated when fifteen years old. The menses were normal, regular, and painless from that time until her nineteenth year, and her general health was exceptionally good. About ten years ago her temperament seemed to change; she became morose and gloomy, shunned the society of her friends, and spent much of her time in solitude. There were periods when she would resume her former habits, but these periods were soon followed by melancholia. While the melancholia was periodic, no relation seemed to exist between

¹ Read before the Kings County Medical Association.

the attacks and her menstrual epochs. Diversion of the mind by constant manual labor made her more cheerful, but she became melancholy again upon being unemployed. She would generally avoid her friends and relatives, and would sit alone for hours masturbating. It has been supposed that her mother's condition aggravated this mental perversion. All reasoning, threats, and bodily restraint failed to prevent the pernicious practice. She would even masturbate in the presence of friends and relatives. Her conversation was silly, and her facial expression stupid. Her general health declined as a result of such unnatural excesses. During the past year she has been under treatment at a sanatorium, without success. Several well-known specialists have advised operation, as offering the only hope of recovery. When seen by the writer she was pale and emaciated, refused to talk, and seemed to enjoy the vaginal examination to which she was subjected. At this time she was masturbating from twenty to forty times a day. Physical examination of the pudendum revealed hypertrophied nymphæ, most marked on the left side. The clitoris was somewhat larger than normal, and the prepuce adherent. The uterus was small and in normal position, and the ovaries and tubes presented no pathologic change. The uselessness of an operation for so pronounced a mental state was fully explained to her father, who, nevertheless, insisted that something radical must be done, and assumed all responsibility. The writer reluctantly consented to operate.

On October 13th, under ether, the clitoris and nymphæ were excised and the labia majora and mucous membrane of the vagina united by interrupted sutures. The vestibule, containing the meatus urinarius, was sutured into the interior angle of the wound, and the line of sutures sealed with iodoformized collodion. Convalescence was uninterrupted and afebrile. The sutures were removed on the eleventh day. Since the operation, three months ago, the patient has shown no desire to return to her former habits; she seems happier, and her mental condition is clearer.

A CASE OF GENITO-URINARY TUBERCULOSIS; NECROPSY.¹

BY HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.;
PHYSICIAN TO BUTTERWORTH HOSPITAL.

On June 8, 1896, I saw, in consultation, a case of genito-urinary disease presenting certain features which I think are of sufficient instructive value to warrant a brief report. The patient was a girl thirteen and one-half years of age. Her personal history was as follows: During the first two years of life she was extremely delicate, after which she developed apparently as well as any other child. At the age of six years she had diphtheria from which convalescence was perfect. One year later she had measles. The parents noticed an arrest of development in the enamel of the permanent teeth as they appeared; otherwise nothing unusual was noticed about her until the latter part of December, 1895, when she complained of

pain during micturition. As this was not relieved by ordinary measures, a physician was called during January 1, 1896, who diagnosed the condition as cystitis. On the opening of school, after the holidays, the patient was well enough to attend for nearly two weeks, but then, the symptoms increasing, she was taken from school, and on January 20th another physician was consulted, who continued in attendance until March 27th. I believe his diagnosis was identical with that of the first attendant. During this time pain upon micturition had increased and then become constant, being referable to the region of the bladder. This pain was controlled by means of opium, and the patient was given sitz baths and diuretic waters.

On March 29th another physician was called, who continued in attendance until May 2d. His diagnosis was paralysis of the neck of the bladder, and he proceeded to cauterize the mouth of the urethra, where the mucosa appeared intensely injected and excoriated. Urinary incontinence had appeared shortly before this, and it continued throughout the course of the disease, there being a constant dribbling when I first saw the patient. Medication was now directed toward improving digestion and nutrition, and cannabis indica was employed, with partial success, to control pain, while daily local treatment was prescribed, though I could not learn in what this consisted.

On the 10th of May, owing to the absence from town of the physician in attendance, another change was made. The child had now been steadily losing ground for four months. Emaciation, constant suffering (which was increasing), incontinence, and the history of the case, alarmed the last-called physician, and a consultation was advised. A surgeon was called who explored the bladder, under chloroform, for stone, with negative results. A gynecologist, who was then called, detected an abdominal tumor among other things, and finally advised microscopic examination of the urinary sediment, suggesting that the trouble might be tuberculous. This was the first time that attention was especially directed to the urine. Owing to the incontinence, only a very small quantity was obtained, which was found to be at least one-half pus. No kidney elements were found. A bacteriologic examination was not made, and as pyuria had been observed before this time, little or no additional light was thrown upon the case.

On June 2d I was called in consultation. Palpation revealed a large, rounded, soft, and fluctuating tumor which filled the right side of the abdominal cavity. The external genitals were swollen and exquisitely sensitive, notwithstanding the patient was narcotized. Eroded patches were present on the walls of the vagina and especially at the meatus. Examination of the thoracic viscera gave negative results. During twenty-four hours about four ounces of purulent urine was collected, analysis of which, as might have been expected, resulted in the detection of a large amount of albumin and peptones and a very insufficient amount of urea. Microscopically, in addition to the pus, I found many epithelial and granular casts and kidney epithelium, although the large amount of pus present made a study of

¹ Read before the Michigan State Medical Society, May 14, 1897.

formed elements difficult. Specimens of sediment stained on cover glasses demonstrated the presence of large numbers of tubercle bacilli in characteristic arrangement. On June 11th the patient died from septicemia or uremia, I am unable to say which was the most active morbid agent.

The autopsy was made on June 12th, from my notes of which I abstract the following important facts: *Thoracic Viscera*.—The lungs, pleurae, heart, pericardium, and upper respiratory organs showed absolutely no foci of tuberculosis, and, aside from the general condition of innutrition, were normal. *Abdominal Viscera*.—The liver, spleen, pancreas, and intestinal tract proper presented no macroscopic evidences of disease. Microscopic sections were not made. Many of the mesenteric glands were enlarged, and microscopic examination proved them to be tuberculous. The peritoneum was free from tubercles. On the right side, the tumor, which occupied almost the entire cavity and pressed the liver upward, and the intestines to the left and outward, proved to be the distorted remnant of the right kidney. All trace of kidney structure proper was lost, and the mass was simply a fibrous, pus-secreting capsule about six inches long by four inches wide, filled with creamy, fluid pus, and communicating with the bladder by a thickened ureter. The pus contained numerous tubercle bacilli, bacilli coli communis, and streptococci. The left kidney presented the evidences, macro- and microscopically, of subacute parenchymatous nephritis, but not of tuberculosis. The left ureter was not diseased except at the bladder. The bladder wall was from one-half to three-fourths of an inch in thickness, the increase being in the mucosa and submucosa. The epithelial layer was almost completely eroded, the vessels were intensely injected, and about the mouth of the right ureter were several ulcers with raised and overhanging edges. The capacity of the viscus did not exceed one ounce. The walls of the urethra were thickened and the mucosa eroded. The condition of the vagina and external genitals was as above described.

I report this case because I believe that it teaches, (1) that renal tuberculosis may be idiopathic; (2) that it may be confined to one kidney and progress to a fatal termination without involving the other kidney in the specific disease, notwithstanding the continuity of the membranous lining—in other words, that involvement of the other kidney does not occur from hetero-infection; (3) that the golden opportunity for cure is lost in the failure to recognize the disease in its early stages before the bladder is involved and when a nephrectomy would promise the best results.

MEDICAL PROGRESS.

A Simple and Accurate Method of Estimating the Percentage of Hemoglobin.—IDE describes in the June number of *Medicine* a ready means of determining the percentage of hemoglobin, by a method more simple and more accurate than any other yet devised. The two methods most in use at present are those of Fleischl and Gowers. Both of these are simple but also inaccurate, while the

necessary apparatus is expensive. The method which Ide has found so satisfactory is that of Hammerschlag, and is known as the specific-gravity method. It is based upon the fact that the relation of hemoglobin to the specific gravity of the blood is practically constant, more nearly so, in fact, than the relation between hemoglobin and the number of red blood-corpuscles.

The apparatus required is simple and inexpensive, and may be easily transported. It is as follows: (1) A hydrometer jar; (2) a hydrometer (or urinometer); (3) a pipette of small caliber; (4) a glass rod; (5) some steel pens; (6) a bottle of chloroform; (7) a bottle of benzol; (8) a bottle containing a mixture of the latter two, and (9) some filter paper.

The procedure is as follows: The mixture of chloroform and benzol (beginning at the first test with equal parts for instance) is poured into the hydrometer jar. The finger tip of the patient is sterilized with a solution of carbolic acid and pricked with a sterile pen from which one of the nibs has been broken. A drop of blood which has oozed from the puncture (not pressed out) is sucked into the pipette, and then gently forced out over the center of the mixture, and shaken off. To avoid mixing air with the blood-drop all the blood should not to be forced out of the pipette, but a little left in its tip. If the blood-drop sinks the mixture must be made heavier with a little chloroform; if it rises benzol must be added. The mixture must be agitated with the glass rod after each addition of either fluid, thus keeping the chloroform and benzol well mixed, and avoiding the breaking up of the blood-drop. When the drop remains stationary, twirling around but neither rising nor sinking, the specific gravity of the mixture corresponds with that of the blood, and may then be recorded with the hydrometer. The same mixture is used indefinitely, the blood being filtered out after each test. The hydrometer jar must be kept absolutely clean, that no fine particles of foreign matter may float in the mixture, and adhere to the blood-drop.

Having determined the specific gravity of the blood, one has only to refer to a table in order to know what percentage of hemoglobin it contains. Such a table is approximately as follows:

Specific Gravity.	Hemoglobin.
1033 . . .	25 per cent.
1035 . . .	30 " "
1038 . . .	35 " "
1040 . . .	40 " "
1045 . . .	45 " "
1048 . . .	55 " "
1050 . . .	65 " "
1053 . . .	70 " "
1055 . . .	75 " "
1057 . . .	85 " "
1060 . . .	95 " "

This table is not entirely accurate but it is approximately so, and has been found reliable at least in anemia, chlorosis, malignant tumors and tuberculosis. At any rate, tests made with the blood of the same patient from day to day will show whether treatment is producing an increase in the amount of hemoglobin. A further advantage of this method is that it does away with the necessity of fine discrimination between different tints.

Tuberculosis and Malignant Disease.—KELYNACK, in a study of the relation between tuberculosis and malignant disease (*Med. Chronicle*, Manchester, June, 1897), found that of 145 cases of malignant disease 22 presented clear evidence of either healed or active tubercle, about 14 per cent., or rather less than the percentage of non-cancerous persons who are affected by tuberculosis. Of these 22, all but 2 had tuberculosis of the lungs. There were 17 cases of carcinoma and 5 of sarcoma. The conclusion is drawn that the victims of malignant disease have not been more subject to tuberculous processes than have "general" cases, and that malignant disease has little or no influence in reviving latent tuberculous processes, or in predisposing to fresh infection.

Simple and Accurate Methods for Detecting and Measuring Abduction and Adduction of the Thigh.—HOFFMANN (*Med. Review*, June 12, 1897) mentions two simple and accurate methods, long employed by him, for detecting and measuring the abduction and adduction of the thigh, which do not necessitate either special apparatus or reference to a table. A slight amount of shortening is often so perfectly compensated for by tilting of the pelvis that its presence is detected with difficulty. If, however, the two limbs be placed together, it will be observed that the anterior furrow at the bend of the thigh on the adducted side is deeper and longer than that on the opposite side; while if abduction be present, the reverse is true. The genitals and the fold between the buttocks will always point toward the adducted thigh. This shows at a glance whether there is abduction or adduction; but it does not determine the degree. This is accomplished in the following manner:

The point midway between the iliac spines is located with a tape-measure, and is marked with ink. A second mark is made directly over the symphysis pubis. This procedure gives two points in the central line over which a string is stretched and continued to the soles of the feet. This string falls midway between the malleoli when the limbs are in a straight position. If either limb be abducted, both the condyle and the malleolus will be outside the string; if adduction is present, they will be inside. The change in position from time to time may be found by measuring and recording the distance of the malleoli from the string.

Disinfection of the Body by Actol.—In the *Centralbl. für Bakteriologie, etc.*, May 10, 1897, MARX describes the result of experiments to determine the disinfecting power of actol (silver acetate), and more especially its power to disinfect the whole body, a property which has been claimed for it by Credé and others. Marx found that it possesses no such action, and that animals which had been subjected to large doses of actol for varying periods of time died as quickly after infection as the control animals. Furthermore, by chemic examination of the serum of animals treated with actol, not a trace of the salt was found. Actol injected into an infected animal had no effect upon the course of the diseased process. It was, however, proved that in a fatal case of anthrax contracted after the silver treatment, the site of the injection was

absolutely free from bacilli. This shows the great value of the drug as an antiseptic, and it is certainly worthy of a further trial.

THERAPEUTIC NOTES.

Kryofin.—Favorable reports of the action of this new antipyretic continue to be recorded. While closely allied to phenacetin in its physiologic action, but 7.5 grains, the usual dose, is necessary to produce a more favorable effect than 15 grains of the other drug. It also possesses analgesic power, and as an antineuralgic EICHHORST (*Deut. Med. Wochenschrift*) has employed it successfully. Kryofin occurs as white, odorless, tasteless crystals, soluble in 52 parts of boiling and 600 parts of cold water. It is conveniently administered in powder form, and enclosed in wafers. No unpleasant symptoms have been observed to follow its use.

The Specific Action of Quinin in Malarial Fever.—At a recent meeting of the North Carolina Medical Society, E. C. Register, M.D., of Charlotte, read a paper with the above title, and stated the following as his conclusions in reference to the action of quinin in the continued form of malarial fever:

Malarial fever without complications will subside after the plasmodia of malaria disappear from the blood; we have in quinin the means to completely eradicate malarial poison from the body; malarial fever occurring in the person of a previously healthy subject, and in the central United States, if at once recognized and properly treated never ends in death; it is speedily curable and never continues, provided the nature of the disease is recognized and appropriate treatment instituted.

As a result of microscopic examination of the blood of a large number of patients suffering from a remittent form of the disease he claimed that the reason quinin does not always produce favorable results in these cases lies in the fact that the drug is improperly administered. He contended that quinin is very imperfectly absorbed when given by the stomach when the patient has a temperature greater than 102° F., but that if the degree of fever is reduced by means of antipyrin, antifebrin or phenacetin, quinin will then cause the crescentic and ring-shaped bodies, the probable etiologic factors in this type of the disease, to disappear from the blood as quickly as it causes the disappearance of the spheric bodies in an ordinary case of intermittent fever.

For Chronic Myringitis.—

℞	Soziodolic acid	gr. vii
	Absolute alcohol	gr. xxx
	Castor oil	3 v.

M. Sig. For external use.

A few drops of this solution are allowed to flow upon the tympanic membrane. By means of its daily application the thickening of this membrane is reduced, and even disappears after three- or four-weeks' use. The soziodolic acid is perfectly dissolved in this mixture of alcohol and castor oil, whereas with other oils, olive oil for example, it simply forms an emulsion.—*The Med. Week.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, SEPTEMBER 4, 1897.

THE IMPORTANCE OF A GENERAL KNOWLEDGE OF BACTERIOLOGY.

THE discovery of bacteria and their place in biology, the consequent complete revolution of many lines of thought, the abandonment of old theories and the establishment of new ones, have occurred so recently, and have followed each other with such rapidity, that much confusion exists in the public mind in regard to the subject. It is this confusion which prevents the accomplishment of the practical results which should ensue from this great acquisition to science. On the one hand there exists a morbid fear of the very name bacteria, on the other there is a skepticism quite as pernicious, and it may be said in passing that the unreliable statements of the newspapers are largely responsible for both beliefs. It is by means of our profession that confusion will be transformed into order. A clear knowledge of the life history of these important organisms will go far to rid the public mind of an unnecessary anxiety, as well as to indicate where the real danger lies, and it is the duty of every physician to disseminate practical information in regard to microbiology whenever practicable.

It should be generally known that bacteria are minute organisms belonging to the lowest botanic orders; that each consists of a single cell, so small that it must be magnified 400 or 500 times in order to be observed; that these minute plants have the power of increasing in numbers very rapidly under favorable conditions by simply dividing into two, each half becoming a fully developed organism like the original; that these plants are, like their larger relatives, some useful and some harmful; that many of these plants have the power of taking in food and converting it into a poisonous substance, just as the deadly nightshade, planted in the same soil and inhaling the same air as its cousin, the potato, will convert its food into poison, while the latter is a most useful food; that the poisonous substances formed by the bacteria, when absorbed by the human economy, produce diseases, modified, among other things, by the intensity of the poison, the rapidity of its absorption, and the location of its inception.

From a strictly utilitarian standpoint we may roughly classify bacteria as (1) useful, (2) harmless or neutral, and (3) harmful. Judging from the sensational articles appearing from time to time in the newspapers, one would suppose that every germ is a disease-producer, and that death to all microbes is a result devoutly to be desired; but, as a matter of fact, the vast majority of bacteria (both as to species and numbers) are either harmless or positively beneficial, the destruction of which would be in the nature of a calamity. Perhaps the greatest benefit which we derive from these little germs is their rôle in the oxidation of organic matter. All dead vegetable and animal matter is acted upon by them, and the complex chemic substances of organic life are reduced to simpler compounds, thus rendering innocuous what might be dangerous, or a least unpleasant, and at the same time furnishing those elements which enrich the soil and make possible the harvest. It has been said that without microbes crops would be impossible (Duclaux).

Microchemistry is a prime factor in the cleansing of water. By its action drinking-water which is contaminated with organic matter is rendered perfectly pure by the conversion of dangerous chemic compounds into harmless nitrites and nitrates; it causes the ripening of cheese; it produces the fine flavors of butter as well as some which are not so fine, and it is probable that

at times bacteria are an aid in the digestion of food. At any rate, there are 331 described species of bacteria which are useful, or at least harmless, and only 158 species which are known to produce disease, and comparatively few of these affect the human family (Sternberg). And, moreover, since the conditions for existence of the disease-producing germs are not abundantly supplied, they have, on the whole, a rather hard life-struggle, and it is not wonderful that when the opportunity presents they improve it to the utmost.

It is the harmful germ with which we are most concerned. The useful germ we accept, like air and sunlight, as a matter of course. The harmful germs, after evading every effort to discover them for centuries, are rapidly being isolated, studied, and the influences which are inimical to their continued existence established. It was found that certain diseases, of which typhus is a type, depended for their propagation on the presence of filth. Measures were taken to remove the filth, and typhus disappeared. It is known that typhoid fever, malaria, cholera, and certain diarrheal affections are produced by the presence of germs in drinking-water, and that if such water is boiled these diseases will be prevented. It is known that the sputum of a tuberculous patient, when allowed to dry, may infect others, and that if the sputum is burned the major danger is avoided. It is known that air-borne diseases are, as a rule, carried but a short distance, and that if a patient suffering from them be isolated, and if all discharges and articles of clothing, etc., with which the patient has been in contact are disinfected, the danger of others contracting the disease is comparatively slight. It is known that certain diseases are prevented or modified by vaccination or inoculation; that this acquired immunity is produced by a well understood scientific principle, which is being repeatedly proven. It is known that for pus microbes, as well as others, there is nothing so conducive to their growth as heat and moisture, and that an old-fashioned poultice supplies these conditions most admirably, and that in the discarding of this dangerous agent for the treatment of open wounds, whether infected or not, and in purulent affections generally, much suffering and perhaps some lives have been saved.

These precepts are thoroughly practical, and even a superficial knowledge of the principles of bacteri-

ology will convince the public of their importance, and the necessity of better measures of quarantine; of the enactment and enforcement of laws in regard to isolation and vaccination; of disinfection; of general sanitary cleanliness, including pure food, pure milk, pure water supply, and pure air; matters in which every individual is vitally interested. The more thoroughly bacteria and their effects are understood, the less we will hear of the scoffer, the anti-vaccination crank, and the mob which resists the health officer in the performance of his duty.

The public is beginning to see that the present practice of medicine is founded on science, and it is anxious to know more of it. It is remarkable what an interest people are taking in this scientific basis of medicine. Whether due to the training in science and physiology now common in our public schools or to some other reason would be difficult to decide, but certain it is that there is a wholesome desire for information which the physician should be the last to withhold. He may communicate the fact to his patients that it is unwise to poultice a boil; that it is necessary to disinfect polluted clothing and diarrheal discharges; that it is desirable to boil suspicious water, etc. Let him also explain to them why these things should be done, and in the majority of cases he will find his audience only too glad to listen, and prompt to obey.

ANTHRAX AND THE DISINFECTION OF HIDES.

THE report of an invasion of the dread disease anthrax at Dubois, Pa., calls attention to the constant danger which arises from the importation into this country of hides, wool, hair, and rags. It appears that the Falls Creek Tannery, located at Dubois, Pa., recently received an invoice of 100,000 hides from China. The hides were started through the process of tanning, and the tanning-fluid drained into the creek which ran near by. Shortly after this several head of cattle which drank the water from the creek suddenly died. Five of the tannery employees were violently attacked about the same time, four of whom have since died. Investigation has revealed the fact that the hides were infected with anthrax bacilli, and the supposition is that the fatal casualties have resulted from an infection from this source.

An invasion of anthrax is comparatively unknown

in this country but the disease is not uncommon in England, where it is generally known as "wool-sorter's disease" or "splenic fever." In Austria and Hungary it not infrequently occurs among people engaged in sorting rags, and is known as "rag-sorter's disease." It is readily transmitted by inoculation, the virus gaining entrance through a wound or abrasion of the skin, and very possibly through the mucous membrane of the respiratory tract. The external form of the disease is known as malignant pustule. The incubation period is short, lasting about three days, and the termination is generally fatal.

In certain parts of Russia, Turkey, and Asia, anthrax is endemic. From these countries are imported Persian wool, mohair, camel's-hair, as well as hides and rags. As little is known in these countries of the infectious nature of anthrax, and as little attention would be paid to it even if it were understood, the wool or hair of animals, dead from this disease, is gathered as well as that from healthy animals. Those plucked from dead animals have frequently portions of skin adherent to them. They are known as "fallen fleeces," and, of course, constitute the most dangerous part of the cargo.

Some recent deaths from this disease among the wool-sorters in England called attention to the importance of proper disinfection of imported cargoes of this character, and careful investigations have been made as to the best methods of accomplishing it. It is found that the diseases most likely to be imported through this channel are the bubonic plague, rinderpest, and anthrax.

In studying the life history of the plague bacillus, Koch and the Bombay commission have confirmed what was already known, that the plague bacillus rapidly dies out. It is only by constant re-inoculations and passage through living animals that the germ retains a high degree of virulence. The voyage, therefore, necessary to reach this country from plague infected districts, as has been pointed out by Doty of the New York Quarantine, would probably be sufficient to destroy the plague bacillus or at least to rob it of its virulence. All material in which it could find habitat may be easily disinfected through the agency of compressed steam.

It has also been fairly conclusively demonstrated that the virus of rinderpest readily loses its vitality

or at least its virulence under similar conditions. In anthrax, however, a much more resistant type of bacillus is presented. The spores of anthrax retain their virulence even after lying dormant for years, nor are they affected by ordinary changes of climate and temperature. It requires very high temperature and great pressure to disinfect packages of baled goods. In the case of rags, wool, and hair, this can be successfully accomplished in bulk, but a temperature sufficient to destroy anthrax spores when applied to bales of hides would materially damage the hides.

As no antitoxin has yet been discovered which will nullify the virus of this malignant micro-organism the only safety for those subject to its invasion lies in prevention. Thus, it is seen that a new problem is presented in sanitary science as practised at quarantine stations. It will be well, if the recent outbreak at Dubois stimulates the government laboratories at Washington, and others as well, to renewed experimentation and inquiry into the resistance of this virulent and dangerous germ.

ECHOES AND NEWS.

Typhoid Epidemic at Arverne, L. I.—It is reported that typhoid, in a mild form, is epidemic at Arverne and Rockaway, Long Island.

Death of Professor Humphreys.—The death is announced of Professor Humphreys, of Johns Hopkins University, at Port Antonio, Jamaica.

The Oldest Russian Medical Society.—The oldest medical society in Russia is the Physico-Medical, which was founded at Moscow in 1804.

International Congress of Hygiene.—The Ninth International Congress of Hygiene and Demography will be held in Madrid, April 10 to 17, 1898.

Appointment of Dr. Warner.—Mayor Strong has appointed Dr. L. Frank Warner, of 139 West Twenty-first street, medical examiner of the Civil Service Board.

Tricycle Invalid Chair.—An invalid chair built on the plan of a tricycle, and propelled by a man on the third wheel behind, has been seen in the streets of Baltimore.

A Doctor a Bank President.—The fact that medical men do have business ability is shown in the election of Dr. James Bordley of Centreville, as president of the National Bank of that place.

Tuberculosis in Cows.—According to an investigation recently made by the Board of Health of New York City, 16.2 per cent. of the milch cows within the city limits are affected with tuberculosis.

A Woman President of a Medical Association.—At the last meeting of the Lehigh Valley (Pennsylvania) Medical Association, a woman, Dr. Mary Greenwald of Stroutsbury, was elected president.

The Next International Medical Congress.—The next International Medical Congress will be held at Paris in the summer of 1900. Professor Lannelongue has been appointed president of the organization committee.

Hot Weather and Suicide.—The great heat which has recently been experienced in Italy has caused an unusual number of suicides, especially in Florence, where forty-four unfortunates have taken their lives since May 1st.

Oklahoma Recognizes Homeopaths.—The physicians of Oklahoma Territory are much exercised over the appointment of a homeopath as president of the Board of Health. An effort will be made to have him removed.

The Statue of Darwin.—A bronze statue of Darwin was recently unveiled in Shrewsbury, England. It has been placed in front of the Free Library, which was formerly the old Shrewsbury school where Darwin was educated.

Diphtheria in Australia.—It is reported that diphtheria is prevalent at Melbourne and throughout the colony of Victoria, Australia. Lack of sanitation and disregard of isolation and disinfection are said to be the cause of the epidemic.

Death under an Anesthetic.—A death is reported from Birmingham, England, during the administration of the A. C. E. mixture taken for the extraction of teeth. Evidence showed that the anesthetic was administered by a skilful physician.

Nurse Dies of Typhoid.—Miss Lucy Jordan Kane, a pupil-nurse in the training-school connected with the City Hospital on Blackwell's Island, New York, died there recently of typhoid fever, which she contracted in the performance of her duty.

The Princess of Wales a "Kneippist."—It is said that the Princess of Wales is taking the Kneipp cure at Woershofen. It is possible that the example set by the Princess may be followed by the smart set, and that the Kneipp cure may become a fad.

Children Paralyzed.—A strange disease has attacked several children in Hackensack, N. J., which results in paralysis of the muscles of the throat and, in some instances, of the extremities. In each case the paralysis followed intermittent fever.

Red Cross Bicycle Corps.—A Red Cross corps of wheelmen, gathered mainly from the different cycle clubs, has been organized in Chicago to give first aid to wheelmen who meet with accidents. The red cross arm-band is the official insignia of the order.

Bacteria Incubating Nursery.—The news comes from London, England, that the vestry of the church of St. Pancras has started a bacteria-incubating nursery, where specimens may be sent for the purpose of bacteriologic examination in suspected cases.

Sickness among Montana Miners.—It is reported that the recent heavy rains in Montana have made the silver-mine region knee-deep in mud. Dysentery has appeared among the prospectors living on this wet ground, due to lack of sanitation and the impure water-supply.

War Against Hat-Pins.—The newspapers of London, England, have declared war against the long hat-pins now worn by women. Two instances are reported in which an eye has been accidentally penetrated by a hat-pin in individuals riding in crowded omnibuses.

A Medical Forger.—A Dr. Brewster, said to be a graduate of the Long Island Hospital College, who for some time past has been swindling medical men in the vicinity of New York, was recently arrested for trying to pass a forged check on the Bayonne Hospital at Bayonne, N. J.

Cause of Death of Napoleon I.—That Napoleon died of malignant disease of the stomach is confirmed by a copy of the *St. Helena Guardian* containing the full text of the report of the *post-mortem*, signed by the medical officers who performed it, recently received by the *British Medical Journal*.

Dr. Mosely Appointed Professor of Gynecology.—Dr. William E. Moseley has been elected professor of gynecology in the Baltimore Medical College. He succeeds Dr. Thomas A. Ashby. Dr. Mosely is a Harvard graduate, and received his early gynecologic training at the Woman's Hospital, New York.

Pencil Sterilizers.—The State Board of Health of Indiana has issued an order requiring all schools to be provided with pencil sterilizers and safety drinking-fountains. The former is a Russian iron oven heated by gas, gasoline, or alcohol, in which pens and pencils are to be heated daily to a temperature of 275° F.

Honor Conferred on Professor Toldt.—The honorable distinction of rector of the University of Vienna for the year 1897-98, has been conferred on Professor Toldt, the celebrated anatomist, who has made important investigations on the development of the peritoneum, and published many important works on embryologic subjects.

Deaths in the Profession Abroad.—The following members of the medical profession have died recently: Dr. R. de Martins Periera, professor of morbid anatomy in the Lisbon School of Medicine; Dr. Victor Mayer, professor of chemistry in the University of Heidelberg; and Dr. Dewindt, president of the Belgium Medical Federation.

Hereditary and Continuous Shedding of the Finger-nails.—The case of a man who, since his birth, has been constantly shedding his nails, was recently reported. The man is an otherwise healthy native of Les Basse-Pyrénées, France. His mother and two of her brothers were similarly affected. The shedding occupies about three months, is accompanied by no pain, and new nails take the place of the old.

A Case of Acromegaly.—A case of acromegaly is reported from Chicago occurring in the person of a teamster. He

presents a very strange appearance, his head measuring sixteen and one-half inches from the upper portion of the frontal bone to the chin. His hands measure fourteen inches from the wrist to the finger tips and are longer than his feet, which have not as yet shown the same abnormal development.

A Cure for Hog Cholera.—The agents of the Chicago, Milwaukee and St. Paul Railroad have been treating hog cholera on a farm near Dubuque, Iowa, with a remedy the nature of which is not mentioned, with the result that during the year fully ninety per cent. of the hogs treated have been cured. As three million hogs died of cholera last year in Iowa, the subject is an important one to the farmer who raises them.

Smallpox in Alabama.—The officers of the Marine Hospital Service sent to Birmingham, Ala., to investigate the smallpox epidemic there, report the disease to be genuine smallpox although not of a virulent type. So far it has been confined entirely to negroes. The sanitary arrangements are said to be excellent. An isolated camp has been established, and a hospital located on the mountain-side at a distance from the city.

Attendance at Moscow.—It is officially reported that 7300 members attended the Moscow meeting of the International Medical Congress. Of this number more than 3500 were from Russia, 800 from Germany, the same number from Austria, 400 from France, 300 from Italy, 300 from England, 120 from the United States, 30 from Mexico, 10 from Japan, 4 from China, and the remainder from other portions of the world.

A Scheme to Sell Spectacles.—A man calling himself "Dr. Frank, of the Manhattan Eye and Ear Infirmary of New York," has been victimizing the residents of Orient, L. I., in the following way: After explaining that he was on his way to a neighboring village to perform an important operation, he told several individuals that they were fast becoming blind and advised them to purchase glasses, which he sold to them at a fabulous price.

A Divine Healer.—Another man who calls himself a "divine healer" has arrived in New York, having ridden all the way from Atlanta, Ga., on a bicycle. He claims to cure the sick, the lame, and the blind by a method "controlled entirely by God." He is wholly without education, but attracts many among the poor and ignorant. Although he boasts that he never asks for a fee, everybody is expected to give what he or she can afford.

Responsibility of Charity Bazaar Fire.—Baron Mackan, the principal promoter of the Charity Bazaar, which was destroyed by fire not long ago in Paris with great loss of life, has just been tried for homicide in neglecting to take proper precautions against fire. He was found guilty of imprudence and fined 500 francs. The cinematograph men were declared responsible for the fire and sentenced respectively to one year in prison and 300 francs fine, and eight-months' imprisonment and a fine of 200 francs.

Statistics of Anesthesia.—The statistics of anesthesia collected by Dr. Gurlt of Vienna, have recently been pub-

lished in the *Journal für Zahnheilkunde*. The administrations reported number 58,769, including 27,000 of chloroform, with 29 deaths; about 19,000 of ether, with 3 deaths; 5000 of Billroth's mixture (morphia, chloroform, and alcohol), without a death; and 5890 of chloroform and ether, without a death. During the last two years 32 deaths have been reported, being 1 death in 1836 administrations.

Hospital Car.—A new hospital car is being constructed for the Long Island Railroad. The car is built like an ordinary Pullman, and has the best system of springs and trucks. There are seventeen cots, and, in an emergency, hammocks may be swung from the ceiling to accommodate ten or fifteen more patients. In one end of the car there is a complete operating-room, fitted up with glass-tables, and all modern surgical appliances. The car will be kept in readiness at all times so that in case of an accident, it may at once be despatched to the scene.

A New Source of Zymotic Infection.—A careful investigation by the New York Board of Health has revealed the fact that the cases of malarial fever and sewer-gas poisoning in the district centering about Fifty-ninth street and Madison avenue are due to the pipes of the steam-heating company. These superheated pipes, passing through the soil in close proximity to gas pipes and sewers, keep the earth at a proper breeding temperature for poisonous germs. As the streets are hermetically sealed by asphalt pavements, the only escape for the confined and contaminated air is along the service pipes leading into the houses.

CORRESPONDENCE.

OUR VIENNA LETTER.

[From our Special Correspondent.]

HOTEL ACCOMMODATIONS AT MOSCOW DURING THE CONGRESS—INCREASE OF INTESTINAL CARCINOMA ACCORDING TO MORTUARY STATISTICS—PROFESSOR NOTHNAGEL AND THE INCREASE OF CANCER AMONG ALL CLASSES OF PATIENTS—SOME OPINIONS AS TO THE PARASITIC ORIGIN OF CANCER—TWO CASES OF AUTO-INOCULATION OF GASTRIC CARCINOMA—PRECAUTIONS AGAINST THE INTRODUCTION OF THE PLAGUE.

VIENNA, August 15, 1897.

THE most interesting topic of conversation among medical men here is the arrangements for the Congress at Moscow. The membership-tickets and free passes on the Russian railroads have come and everything promises a very pleasant time. There is one little cloud on the horizon, however, and as a number of Vienna medical men attended the International Congress at Rome three years ago, it looks darker to them than to the untraveled. Those who have received notices that rooms have been reserved for them, as requested, say that charges are very high. To an American who realizes that, as a rule with us, during such assemblies special rates at hotels are given to members of the associations, it seems hard that there should be a considerable advance in price on such an occasion. This seems to be the general expectation

here, however. As hotel accommodations in Moscow, despite its population of more than three-quarters of a million, are rather limited, it is possible that there may be some inconvenience experienced in securing comfortable lodgings, and rates will be correspondingly high. This may really be only a false presentiment, however, such as is liable to occur when a journey into the unknown is contemplated. The committee of arrangements has given complete satisfaction so far by its management of things, and it is more than likely that every effort will be put forth to show the visitors that the much-lauded Russian hospitality is not an empty phrase.

Here, where every interesting fatal case comes to autopsy, one of the most striking things in the section-room is the comparative frequency of intestinal cancer. Every ten days or two weeks at least one case of the disease turns up. Professor Nothnagel, in the last clinic of the year, called attention to the fact that the frequency of the occurrence of cancer seems to be on the increase, but that this is especially true of the intestinal form. That this is not apparent but real is proved by the statistics of the Pathological Institute of the General Hospital. During the twelve years from 1870 to 1881, inclusive, one hundred cases of cancer of the intestine were reported *post-mortem*, while during the twelve years from 1882 to 1893, the number had risen to 242, nearly $2\frac{1}{2}$ times as many. This is a startling increase and might be thought to be due to other factors, besides increased frequency of the affection itself—to more careful diagnosis for instance, to the fact that more cancer patients came to the hospital, as the prejudice against hospitals on the part of the poor has been gradually becoming less during these later years, or to the retention of more cancer patients until the fatal termination, or even to such extraneous considerations as change in the character of the patients who have come to the hospital, or to an increase in their number. All of these Professor Nothnagel excluded. He has been connected with the hospital in important capacities during all of these years, and he is sure that the character of the patients is not different from what is used to be. The number of patients has not materially increased, and their period of retention is about what it used to be. The conclusions from the mortality statistics are confirmed by the fact that a corresponding increase of the number of all patients in whom intestinal cancer was diagnosed, including those, therefore, who did not die in the hospital, has also taken place. A fair proportion of cancer cases when it becomes evident that the affection is hopeless prefer to die at home, and so do not enter as a factor of the mortality statistics.

It is not alone in hospital cases, however, that this increase of intestinal cancer has taken place, for it is not confined to the poorer classes. Professor Nothnagel recalled a private conversation with the late Professor Billroth during 1893, in which they were in accord in thinking that a startling increase in the number of cases of intestinal cancer in their private practices had also taken place.

The increase noted—*post-mortem*—during the twelve years from 1882 to 1893 has continued since, and every

year the number grows larger, so that the next twelve years promise to show a still larger number, actually and comparatively, of deaths from intestinal cancer. The same condition of affairs obtains also for cancer in general. The increased frequency of cancerous affections has, of course, been reported elsewhere. In England attention was called to it several years ago. The German statisticians have shown that cancer is also seemingly on the increase in many parts of their country. Recent French statistics point to the same conclusion. Most statistics, however, included so heterogeneous a collection of cases that their value could be impeached by such considerations, as that better diagnostic methods and more faithful reports have added to the number of recorded cases, but that the affection itself was probably not more frequent than formerly.

These Vienna statistics, however, would seem not to be open to these objections, and are not the result of a series of cases collected for the purpose of proving or disproving a theory. They are simply the report of *post-mortem* findings covering many years, where the same methods of examination always obtain. It would seem to be beyond cavil then, that cancer in its worst form and in a situation where least can be done for it with reasonable hope of success, is becoming startlingly more frequent among all classes of patients.

With a field like this for investigation of the etiology of cancer one is surprised not to find more new theories as to its probable origin. They cling very conservatively here to the older explanations, such as they may be, and only turn to a new theory occasionally when some one else has been bold enough to advance it, and then but to show its falsity. While most of the medical world is gradually coming to the opinion that the cause which produces a malignant multiplication of epithelial elements is parasitic in nature, most of the authorities on pathology here shake their heads very dubiously, and say they find no reasons for holding such an opinion. Professor Metschnikoff at the Pasteur Institute definitely asserts his belief in the parasitic origin of cancer, and considers that it will be found to be a form of protozoön. The Italians have been interesting themselves lately in the theory that it is a blastomycete, a form of yeast, and I saw, through the kindness of Dr. Roncalli in Rome, a series of specimens which illustrate the theory very beautifully. The readiness with which articles discussing a parasite of cancer are accepted by the German medical journals generally is an index of what the German trend of thought in regard to the subject is. Despite all this one hears very little of the parasitic theory here.

Professor Kollisko in a recent demonstration showed two very interesting cancers of the stomach, where it was evident that there had been auto-inoculation. On the posterior wall of the stomach in each case was a cancerous nodule about the size of a walnut. On the anterior wall, but separated from the first by an inch or more of healthy tissue was a second, smaller nodule. The second was evidently not a metastasis; much less was it due to any infiltration in the continuity of the tissues. The anterior wall in both cases, while the stomach was empty,

had collapsed against the site of the nodule on the posterior wall, and the abnormal pressure so set up had caused slight injury to the mucosa, at which place there occurred an infiltration of cancer-cells from the superficial portions of the primary growth.

Such an occurrence has been described before, and is just such another condition as occurs under similar circumstances when both lips become affected with cancer, or two adjoining skin surfaces, as the folds beneath the breast, become successively infiltrated as the result of contact. The condition has been used with supposed effect as a proof of the contagious nature of cancer, and as all contagion of which we know is of parasitic origin, it follows that this condition may be taken to indicate the presence of parasites.

Professor Kollisko showed that it was merely a transference of epithelial elements already predisposed to atypical overgrowth—a true metastasis, not through blood or lymph, but from tissue contact. As in ordinary metastasis it is, as a rule, an overgrowth of transferred elements which occurs, not the irritation of a new focus causing cancerous degeneration, and so the question would seem to remain where it was years ago when the original theories of cancer etiology were advanced.

Despite the fact that the Government Pest Commission reported that there was little chance of the introduction of the pest into Europe, since the contagion is not carried in fomites, a conclusion with which the German Commission fully agreed, the health authorities consider it necessary to take special precautions. For this purpose Professor Weichselbaum, the official pathologist, has been asked to furnish the data necessary for the immediate recognition by health inspectors of the pest bacillus in suspected cases. He has also been asked to open a course at the Pathological Institute, in which the peculiarities of the bacillus will be practically demonstrated, so that cases may not escape detection at the very beginning should they occur, and so prevent the possibility of an extensive infection.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held at Montreal, August 31 to September 3, 1897.

[Special Telegraphic Report to THE MEDICAL NEWS.]

GENERAL SESSION.

FIRST DAY—AUGUST 31ST.

NEVER did the British Medical Association convene under brighter skies or with more cordial surroundings. The internal conditions of the gathering are fully in accord with the environment; for the body of members from the mother country is large, the American profession has freely responded to the invitations courteously extended by the local committee, and the Dominion members swell the tide, until, at the close of the first day, some 1600 are recorded as in attendance, a number which compares favorably with that usually found at sessions held within the sacred limits of the "Little Island," which

nearly all now in attendance regard as the "old home country," either directly or ancestrally.

The session was opened after the old fashion by a special service in the great Christ Church. It was a most graceful and impressive ceremony on the part of the Association, and to the anthropologist a pleasing reminder of the common lineage of the two great professions, theology and medicine. To observe a congregation made up two-thirds of men was in itself impressive, and the beautiful music, and the appropriate sermon by Bishop Domoulin made the occasion one long to be remembered.

Early in the afternoon the delegates and guests filled the large auditorium, Windsor Hall, to overflowing to listen to the speeches of welcome and the President's address. (See page 289.) The platform was occupied by the speakers and other celebrities, among whom were Lords Mount Royal and Lister, Sir William Hingston, and Dr. Charles Richet of Paris. It was an enthusiastic audience, especially in its loyalty, every reference to the mother country, the Queen, and the glories of Canada, being applauded to the echo. But no single burst of applause exceeded that which greeted Dr. Roddick's graceful tribute to Lord Lister. The President of the Association, Dr. T. S. Roddick of Montreal, introduced the Mayor of the city, who cordially welcomed the delegates. He was followed by Sir Adolphe Chapleau of Quebec, who, in eloquent and impressive language re-echoed the former speaker's words of welcome. The Earl of Aberdeen, Governor-General of Canada, then, as he expressed it, thrice welcomed the members of the Association to its first place of meeting beyond the confines of the British Isles, and in a brief but witty speech made every one feel that his welcome was a personal as well as an official one.

At the close of Dr. Roddick's address Lord Lister moved a vote of thanks and took occasion to compliment the Canadian members upon their lovely country and healthful climate, which made it seem to him one vast health-resort. He sympathized with the President with reference to the difficulties of medical legislation regarding license to practise, and expressed a preference for the English method, in which teachers are represented in the examining-boards, as freest from objections. He begged to express the gratitude of the members of the British Medical Association for the cordial welcome and magnificent hospitality extended to them. Sir James Grant of Ottawa seconded the vote of thanks.

The secretary, Dr. Adami, then read the names of the delegates representing the various branches of the Association throughout the empire, and from the various State and National societies of the United States, and each delegate came forward in turn and was presented to the president, and by him to the Earl of Aberdeen. The address of the president completed the session.

A trolley ride around the city was then indulged in, and, later, a reception by Dr. Roddick and his daughter was held in the handsome rooms of the Art Gallery. One of the pleasantest events of the day was the dinner tendered to Lord Lister by the Medico-Chirurgical Society of Montreal. About three hundred members and guests were present, and at its conclusion the president of the

Society, Dr. George Wilkins, presented the guest of honor with a bound, illuminated Address expressive of the esteem in which his great discovery of antiseptis is held by the profession. In accepting the gift, his lordship expressed in a few well-chosen words his appreciation not only of the Address itself but of the kindly feeling which had prompted its preparation.

In the evening a reception and *conversazione* was held at Laval University, after which PROFESSOR CHARLES RICHTER, delegate of the French Government and of the Faculty of Medicine of Paris, delivered in French an eloquent address upon

THE WORK OF PASTEUR AND THE MODERN CONCEPTION OF MEDICINE.

The speaker clearly set forth the change which has been wrought in placing the practice of medicine on a purely scientific basis. The credit of this is largely due to Pasteur. Upon his discoveries rests the entire structure of experimental medicine. The logical succession of events in Pasteur's work were traced in a graphic way from the first discovery of the biologic basis of fermentation to the demonstration of the principles of immunization by attenuated virus.

The great fact of the generation of germs was absolutely unknown before Pasteur. The inoculation of liquids with spores and the method of sterilization was revealed to us by Pasteur. It is the nature of great discoveries that they become popularized quickly and thus become elementary. A first-year's medical student knows perfectly that which neither Lavoisier nor Leibig, nor Férmy nor any one before Pasteur had been able to perceive. Great discoveries fall rapidly within the domain of common knowledge; they become so simple that they cease to surprise us.

It is true that Pasteur did not discover all the microbes of all contagious diseases, but this is of small moment, since he was the first to discover that infection was a phenomenon of microbial parasitism. All those who after him have proved points of detail, however important or fundamental they may be, have but followed the path traced by the master. Whether they will or not, they are all the pupils of Pasteur, as those who follow the study of chemistry are pupils of Lavoisier.

The greatest of Pasteur's disciples, Robert Koch, although with some ingratitude he refuses to recognize his master, has only perfected certain points in technic and applied his ingenuity and his perspicacity to the solution of questions which in spite of their practical importance are still secondary. He has not, in fact, been able to do anything new except upon points of detail, all that is essential comes from Pasteur himself.

It need not be said that this idea of the microbe, of the parasite, has become the basis of medicine. If we take up treatises on pathology written before this prodigious revolution, we shall be astonished by the insignificance and the nothingness of these very ancient books. Yet they are not really very old, they are dated 1875 or 1880, but as one reads them it seems as though several centuries must have intervened between these venerable writings and modern books.

In ten years medicine has been entirely overturned and re-made. It is being re-made every day. Every day brings some new discovery in matters of detail, but the great principle is always there, and it must always be attributed to the one initiator.

Fermentation, infection, contagion, vaccination; here in four words we have the work of Pasteur. What more need be said? Do not these four words possess, in their simplicity, unequaled eloquence?

Can any one longer maintain that the progress of medicine is not due to experimental science? Does not all this knowledge of microbes and of the part which they play in disease imply, immediately and necessarily, immense progress in therapeutics?

Pasteur was spared to take part in the triumph of his ideas, and to be a witness of his own glory. If, like so many creators, he had sometimes in his earlier days known conflicts and hatreds and petty quarrels and foolish objections, nevertheless he had not to deplore the ingratitude of mankind. He died full of honors, surrounded by admiration, respect, and love.

And now let us turn back to consider the indisputable union of medicine and science. This, in fact, is what ought to strike us in the work of Pasteur. It is not only in general biology and in the progress of our knowledge that his work is great, it is still more in its immediate practical applications. The great biologists of our century, Lavoisier, Claude Bernard, Darwin, have, without doubt, left behind them work which, by reason of its conquests of new truths, is not inferior to the work of Pasteur, but these new truths do not lead to any such immediate application as antiseptis, the treatment of hydrophobia, anthrax, vaccination, or the prophylaxis of infectious diseases. Pasteur was not only a man of science, he was also a benefactor, and there is scarcely one who can be compared with him as a benefactor of suffering humanity except Jenner, who found out how to preserve thousands and thousands of human beings from the most hideous of diseases.

Serum-therapeutics is a direct sequence of the labors of Pasteur. This is a mode of treatment born of the experimental method alone. Here again science has done for the art of medicine that which clinical observation, left to its own resources, could never have accomplished.

A German experimenter, Behring, after studying the effects of the serum of refractory animals upon diphtheria, showed (in 1892) that this serum is wonderfully efficacious in the treatment of the disease. He applied the serum method of treatment not only to diphtheria, but also to tetanus, and, at first in animals and afterwards in man, he obtained results which were really marvelous. Gentlemen, you know the rest, and I need not tell you that this serotherapeutic method, improved and popularized by Roux in 1894, is now a treatment without compare. The statistics on this head are absolutely conclusive. The mortality of diphtheria, which was forty-five per cent., has fallen to fifteen per cent. That means for the city of Paris alone an annual saving of about 1000 human lives; for the whole of France, nearly 10,000 lives. We may take the same proportion for Italy, Germany, England,

the United States, Canada, and Russia, and may estimate the number of infants which serum-therapeutics annually snatch from death at about 50,000.

The last word has not yet been said about serum-therapeutics. The organism is endowed with a marvelous power of resisting the poisons secreted by microbes. It sets to work in its turn to secrete counter-poisons which neutralize the poisons secreted by the microbe. The antitoxins of the organism combat the toxins of the parasite, and in the future the art of serum-therapeutics will be to seek in these resisting organisms the antitoxins fabricated by their cells.

Thus on whatever side we turn we find that medicine has always been guided by experimental science. By experiment and by science it is compelled to march forward. This was true in the time of Harvey, for that immortal physiologist had to meet the opposition of physicians. This was true also in the time of Lavoisier, when by a few decisive experiments he proved the chemic nature of the phenomena of life. But how much more true is it at the present time since Claude Bernard, and above all Pasteur, have by experiment laid open a whole world and have warranted us in conceiving the widest hopes for the future of medicine.

The part of the man of science and of the physician are very different. The physician ought to be conservative, applying methodically the teachings and precepts which he has received. He has no right to experiment upon his patients, or to permit human life or human suffering to be risked on fantastic theories. But the man of science ought to be a revolutionist. He ought not to be content with the doctrines which he has been taught. The opinion of the master ought to be but a light weight upon his mind. He should seek on every hand for facts which are new and even improbable. Darwin says somewhere that he had made the experiments of a fool, and often it is right to attempt that which appears contradictory to all established and classic opinions. Without this spirit of adventure, without this scientific daring which opens up new horizons there is no progress.

The task of the explorer or of the pioneer is not that of the physician. He ought to be careful to keep himself abreast of all scientific progress in order that his patients may have the benefit of it, but he cannot advance the progress of science, save within restricted limits. Having no right to experiment he is almost powerless to solve the difficult problems which arise.

It is the duty of the chemist, the physicists, and above all the physiologists, to guide medicine into the new ways. They have not to take the heavier responsibility of a human life upon their shoulders, and nothing should check their audacity. You, gentlemen, have not the right thus to be audacious; you need prudence and moderation, and, convinced as I am of the power of experimental science, I still think that the applications which the chemist or the physiologist suggests to you should only be accepted with considerable caution. It costs us nothing, after a few experiments which have succeeded fairly well, to say to the physician, "Try that on your patients," knowing very well that our responsibility is

nil, and that the ancient axiom *primo non nocere*, an axiom which ought to be your strict rule of conduct, does not in any way apply to us. You see, therefore, that it would be unjust to make it a matter of reproach to physicians and surgeons that they have not made great scientific discoveries. This is not their mission. It is theirs to relieve human suffering and to seek among new scientific truths that one which is most proper to relieve or to cure the sick.

SECOND DAY—SEPTEMBER 1ST.

The event of the afternoon was the Address in Medicine by DR. WM. OSLER of Johns Hopkins University, Baltimore, (see page 293), whose selection for this honor was a most graceful compliment to the entire medical profession on this side of the line. He commanded the closest attention, and was often interrupted by demonstrations of approval. At the close of the address the honorary degree of LL.D. was conferred by McGill University upon the following members of the British Medical Association: Lord Lister, Sir Wm. Turner, Sir Walter Foster, M.P., Professor Michael Foster, Dr. Henry Barnes, Mr. Christopher Heath, Dr. R. Saundby, Mr. C. G. Wheelhouse, Dr. W. H. Gaskell, and Professor Alex. McAlister, and upon Professor Chas. Richet of Paris, France. The degrees were presented by the Chancellor, Lord Mount Royal. At four o'clock in the afternoon a large party made the celebrated trip through the Lachine rapids, while others of the members attended a charming garden-party in the grounds at the Royal Victoria Hospital. In the evening a reception was tendered the Association by "The Man Who Owns Canada," Lord Mount Royal and Baron Strathcona (since the Jubilee), better known as Sir Donald Smith.

SECTION IN GENERAL MEDICINE.

FIRST DAY—SEPTEMBER 1ST.

DR. STEPHEN MACKENZIE of London, England, the President, opened the Section with a review of the progress of medicine since the establishment of the British Medical Association. He complimented the profession upon the fact that the progress during recent years has been as beneficial in the prevention and treatment of disease as it has been scientific and rational in character.

DR. JAMES STEWART of Montreal opened the discussion on the subject of

ARTHRITIS DEFORMANS,

basing his observations on forty cases treated at the Royal Victoria Hospital during the past four years. Thirty per cent. of the male patients had a history of gonorrhea. He discussed the relation of rheumatoid arthritis to rheumatism, nervous diseases, and tuberculosis. One-third of the patients gave a history of antecedent acute or sub-acute rheumatism, and these cases would seem to have been a transition or development from that condition. He believed that evidence is accumulating to show that both ordinary rheumatism and rheumatoid arthritis are of microbic origin. He did not think there is any specific causal relation between rheumatoid arthritis and nervous or tuberculous disease other than the fact that the de-

pression incident to these diseases will predispose and lessen the resistance of the system to this or any other infection. During the past nine months he had employed superheated air baths, with good results, in the treatment of rheumatoid arthritis, in some twenty cases, at the Royal Victoria Hospital.

DR. H. HANDFORD, Nottingham, England, claimed that rheumatoid arthritis is purely an arthritis and has no relation whatever to rheumatism. The frequency of antecedent gonorrheal infection, as noted in the cases of Dr. Stewart, would argue in favor of a pyemic infection of the joints in this disease. He believed the affection to be of microbic origin. He had found that carbonate of guaiacol gives good results in the acute stages. Dr. Lindsay of Belfast, Ire., was a firm believer in the intimate relation between ordinary rheumatism and rheumatoid arthritis, and he relies chiefly upon tonic treatment in both diseases.

DR. WILLIAM OSLER of Baltimore referred to the atrophic nerve changes which frequently follow and possibly result from the disease.

DR. A. JACOBI of New York maintained that there is a distinct pathologic difference between polyarticular rheumatism and rheumatoid arthritis, inasmuch as in the former the lesions are confined to the synovial membrane and in the latter to the cartilages, this fact alone constituting a dividing-line between the diseases. He thought both diseases may be best studied during childhood. His best results have been obtained from the long-continued use of arsenic.

DR. J. C. WILSON of Philadelphia would confine the term "rheumatism" to cases with arthritis lesions only.

DR. F. C. SHATTUCK of Boston had found concealed suppuration a very frequent starting point of rheumatoid arthritis.

DR. MOOREHOUSE of London, Ontario, adhered to the theory of the intimate relation of rheumatism and rheumatoid arthritis, and has found supportive treatment, cod-liver oil, etc., valuable in both conditions.

DR. J. E. GRAHAM of Toronto drew attention to the difficulty of differentiating this disease from gouty conditions. Arsenic has given the best results in his hands.

DR. GRIFFITHS of Swansea, Wales, looked upon the disease as a development of various deleterious conditions, such as shock, bad food, and ventilation; not as a disease *per se*, but rather as a result of certain local influences. Accordingly, the rational treatment should vary with the general indications so as to combat the exciting or predisposing causes.

DR. V. P. GIBNEY of New York referred to the necessity of putting the joints at rest by mechanic appliances during the stage of exacerbation, and subsequently regulating the degree of movement when resolution appeared to set in. By this means relapses from trauma will be prevented.

DR. JAMES TYSON of Philadelphia believed in the microbic origin of the disease.

The PRESIDENT expressed his pleasure at the freedom with which divergent views had been advanced, and believed that ultimately, as a result of independent investi-

gation, unanimity of opinions as to the character of this obstinate disease will be attained.

DR. TYSON then read a paper on

THE PROPER USE OF TERMS TO DENOTE MYOCARDIAL CHANGES.

DR. J. T. WHITTAKER of Cincinnati, and DR. N. S. DAVIS of Chicago discussed the paper. The latter emphasized the utility of the terms "cardiac fatigue" and "cardiac exhaustion" in relation to the chemic and anatomic changes incident to these conditions.

DR. M. H. FUSSELL of Philadelphia reported two rare cases of hemophilia occurring in children of the same family, having a hereditary (paternal) history. Bleeding of an alarming character would result from the slightest injury, and prolonged epistaxis without cause was a frequent occurrence.

DR. ACHESON of Galt, Ontario, read a paper on

ATONY OF THE RECTUM.

differentiating it from chronic constipation due to mere impaction, and condemning the too frequent use of enemas, especially of warm water.

SECTION IN SURGERY.

FIRST DAY—SEPTEMBER 1ST.

MR. CHRISTOPHER HEATH of London, the President of the section, delivered the annual address, entitled

ON THE TEACHING OF SURGERY.

The speaker expressed the honor he enjoyed in presiding over the section, and especially over colleagues of such eminence as were represented by the vice-presidents of the surgical section. He also acknowledged the pleasure felt in meeting the Canadian members of the profession, as well as those medical brethren from the United States who attended the meeting, and he trusted that the deliberations of the section would not merely advance the science of surgery, but would cement those bonds of fellowship between the members of a united profession, which a common Anglo-Saxon origin should foster and maintain.

After dwelling somewhat at length upon the remarkable strides taken by abdominal surgery during recent years, the speaker turned to the subject of modern anatomic instruction. He said, "I am told by those who are now teaching anatomy that it is difficult to get the student to make a neat dissection, because he can find in the various museums, and notably at the College of Surgeons of England, such beautiful preparations in spirit that he prefers to study from them or from pictures rather than to laboriously extract the details for himself. If this be true, I can only regret that the present race of students is so shortsighted, for without a working knowledge of human anatomy I can conceive of no progress in surgery. I regret to find that, in Great Britain at least, the teaching of anatomy is gradually getting more and more into the hands of professors who are anatomists but not surgeons, and that their tendency is to lay stress upon transcendental details rather than surgical relations."

The speaker asked, Are we not overdoing the scientific teaching of a man who has, after all, to get his living as

a practitioner of medicine, surgery, and midwifery? When the medical curriculum was lengthened by a year it was hoped that the additional time would be devoted to clinical work, but he feared that such is not always the case. He disclaimed it as his intention to decry the modern methods of teaching medicine in the wards of the hospitals, and he praised the practical methods of teaching percussion and auscultation, and spoke of the time consumed in the other departments as leaving but little place for surgery; he lamented that so small a portion of the course is devoted to this important branch, and all of which is in contrast to the fact that there never has been a time of such great surgical activity as now.

In conclusion he said, that "still the great foundations of the art of surgery remain unshaken. Without a knowledge of anatomy, pathology, and histology progress in surgery is impossible, and it is for those who hold the important positions as teachers in the great medical schools to insist that each and every student be provided with a foundation of scientific and practical training, if they are to become the surgeons of the future."

The President then introduced the topics selected for general discussion at this meeting, *viz.*: Appendicitis, and Cancer of the Rectum.

APPENDICITIS.

The opening paper was by DR. G. E. ARMSTRONG of Montreal, who said that the introduction of this subject would give opportunity for English and American surgeons to compare their rather widely different views on this widely discussed topic. The paper was based on 517 cases occurring in the Royal Victoria and Montreal General Hospitals, mostly in patients from twenty to thirty years of age, there being about two males to one female. With respect to the etiology of appendicitis, it is only to be said that anything which destroys the epithelial lining may produce inflammation. Doubtless, stercoral ulcers are responsible for many cases. Before 1889, these patients were all admitted to the medical wards, but since then to the surgical. In these 517 cases, the mortality was 12½ per cent. An operation was performed in each instance. One hundred and fifty-two cases gave a mortality of 23 per cent., about twice that of the cases as now treated. Of these 517 cases, the mortality of those not operated upon was 3.12 per cent.; those operated upon in the acute stage was 20 per cent.; those operated upon in the interval all lived. Sixty-five fatal cases were septic and tubercular; peritonitis, with abscess of the liver, etc., caused the death of 61. Septic pneumonia and Bright's disease were responsible for death in 2 instances.

In the case of several patients with "idiopathic" peritonitis who died no lesion could be found at autopsy, and a similar case occurred in a woman who went skating during a menstrual period, so that the term "idiopathic" cannot be banished altogether. The best time to operate is a difficult question to settle. In some cases the attack is so mild that no operation is necessary; in others the condition is so grave that no operation can give relief; but the great majority of cases are now seen between these extremes. The cautious surgeon will operate early, only the bold and

reckless will advise delay. A case was mentioned as occurring in a young professional man, which progressed six days, with scarcely any symptoms. He was forbidden to get up, but did so, and going to the water-closet ruptured a pericecal abscess, and in spite of almost immediate operation died of septic peritonitis. The rule is to urge operation if all symptoms are not much improved after twenty-four or thirty-six hours have elapsed, and if the patient is not very much better by the third day there is every reason to operate. In general septic peritonitis, thorough washing with hot normal saline solution is non-irritating, and is successful in removing the pus and fibrin. Three large drains, one in each loin and one in the pelvis, will prevent accumulation of fluid.

In localized abscesses, the removal of the whole of the abscess-walls gives the best results for several reasons. In the first place, this procedure avoids the not too rare danger of leaving other abscesses undiscovered. Another reason is that septic material is in this way removed from the mesenteric and omental veins. This avoids the danger of poison proceeding to the liver or spleen, and the production of secondary abscesses. In a hospital, the peritoneal cavity can be so protected with gauze, etc., that there is virtually no danger of a general peritonitis being produced by this radical treatment, while in private practice it may be necessary for the surgeon to content himself with evacuating, cleansing, and draining the abscess.

DR. J. WARD COUSINS of Southsea, Wales, freely endorsed Dr. Armstrong's statement that no special set of symptoms will surely indicate the course appendicitis will take. No statistics will help at the bedside, where each case must be studied by itself. In the cases which recover without operation, the pain first disappears, then the distension, and later the tenderness. The induration does not point with any reliability to the direction in which the abscess is proceeding. If there is the smallest increase of pain, operation is indicated at once. In order to get the best view of the cecal region after the incision has been made, the introduction of a couple of silk sutures through the edges of the wound is far better than the use of retractors. Contrary to the advice of Dr. Armstrong, the speaker believed in carefully wiping out and draining an abscess, without breaking down its walls. He never irrigates, never pulls out the intestine, and opposes the use of drainage-tubes.

DR. C. B. BALL of Dublin said that there are three classes of cases in which operation was agreed to by all: (1) When peritonitis has already developed; (2) when abscess has definitely formed; (3) when repeated attacks have rendered life a burden. In other cases, even during the first attack, there is a very wide difference of opinion as to the value of operation. The speaker cited an instance in which a patient who was doing well for several days died very suddenly from perforation. Such cases, he said, are decidedly rare, and most patients recover without operation. In a great majority the first attack is the last.

MR. JORDAN LLOYD of Birmingham, England, said that it would simplify matters if one were able to divide all cases into (1) appendicitis, strictly speaking, in which

the inflammation is confined to the appendix, and (2) those in which the peri-appendicular tissues are involved. He considered the swelling a most reliable guide to the position of the tip of the appendix, an organ whose length and location varies much in different individuals. In some seven or eight cases in which a long appendix had caused a pelvic abscess, the reader had imitated what frequently occurs spontaneously, and drained the abscess into the rectum in men, and the posterior vaginal cul-de-sac in women. In opening abscesses through the abdominal wall, he hesitates to employ the radical treatment advocated by Dr. Armstrong, but treats the abscess as gently as possible. Iodoform gauze makes a much better drain than either rubber or glass.

DR. WILLIAM HINGSTON of Montreal agreed in this opinion. He also expressed his satisfaction at hearing one speaker object to the advocacy of so serious a thing as an operation to establish a diagnosis. Men are sometimes too slow to see a way out of a difficulty by any other than an operative route. He has operated in only about one out of ten cases of appendicitis, and has never had occasion to regret not having operated in the other nine. If it is most satisfactory to operate for the benefit of a patient, it is still more so to bring a patient safely through a serious illness without an operation.

DR. ALBERT VANDER VEER of Albany insisted upon the importance of observation of the early points in an attack of appendicitis. He indorsed the plan suggested by Dr. Armstrong for the thorough removal of all infected material about an abscess. McBurney has laid too much stress upon a particular point of tenderness; this may not be found and much valuable time be lost. Statistics are valuable in many ways, but each surgeon must depend more upon statements made to him by the particular physicians who call him in consultation. Cases also vary in different seasons of the year. In cases of general peritonitis some good results have been obtained from wiping off the intestines with gauze, etc., but the greatest improvement in results is to be hoped for from getting into close touch with the family physicians, so that they may be able to present a patient for operation at an early stage.

DR. HUGH FERGUSON of Chicago said that appendicitis is almost exclusively a surgical affection, and that the cases which are not surgical are very rare. It is a good rule not to operate at the climax of an acute attack, as the results are better when the operation is done either before the inflammation has reached its height, or during its decline. In all recurrent cases operation is clearly indicated, as no one can tell when an attack may supervene and prove fatal. Between attacks the McBurney incision, separating the fibers of the muscles longitudinally, so as to avoid subsequent hernia, is recommended. In the case of abscesses, the speaker objected to the practice of breaking down adhesions in the search for the appendix. During the early stage it can almost always be readily found; later, it is better not to hunt for it. Flushing out the cavity gives better results than mopping with gauze. In septic cases, when the patient seems likely to die from absorbed poison, saline transfusion has been tried, with unsatisfactory results.

DR. S. C. GORDON of Portland, Maine, believes in treating appendicitis in the beginning, medicinally. It is a beginning peritonitis, and in ninety per cent. of the cases a saline cathartic will carry the patient safely through an attack. Operation is to be recommended in these cases after the acute attack has passed. The objection has been made that the vomiting prevents the administration of a saline. Usually, two Siedlitz powders, or a concentrated solution of Epsom salts, may be taken; if not, the latter with glycerin may be administered by the rectum, and a movement of the bowels obtained. If after the bowels have acted, the temperature continues to rise, an operation must be performed. Generally, in these cases pus is found. Morphin should never be given for the pain. It is better to suffer agony than death, and if the doctor remains by his patient's side, and administers a saline in a hot concentrated solution, it is gratifying to see how rapidly pain will subside. To rid the bowel of the accumulated fecal matter is of great advantage in the case of a patient who is to be operated upon later. A certain number of patients are bound to die from the first, no matter what is done.

The PRESIDENT expressed his satisfaction at hearing the expression of Dr. Gordon's sentiments, which coincided with his own. In a number of cases he had refused to operate upon patients, who subsequently recovered. The pain can be relieved by painting the region of the cecum with belladonna, and then, if necessary, covering this with a good old-fashioned hot flaxseed poultice. The patient should be kept in bed just as carefully as though suffering from typhoid fever.

DR. ARMSTRONG, in reply, said that he has tried drainage with gauze in every way that had ever been advocated, and he had never been able to get it to drain pus. He has repeatedly found pus at the end of a gauze drain which it refused to draw up. A large glass drain is much more satisfactory. He also uses poultices and finds them of great advantage in relieving the pain.

DR. A. E. GARROW of Montreal then read a paper upon

VENTRAL AND UMBILICAL HERNIA IN THE SAME PATIENT,

a very rare condition, at least judging from the published cases. In his case the ventral hernia contained the cecum, appendix, small intestine, and omentum, while the umbilical hernia contained only a single knuckle of small intestine.

DR. ALEXIS THOMPSON of Edinburgh spoke of stricture of the intestine as a sequel of strangulated hernia. If the obstruction is due to peritoneal adhesion, causing a kinking, the symptoms will be more acute, while if it is due to a band, they will come on more gradually. A man who had had an inguinal hernia for several years, and in whom strangulation had existed for three days was found with viable strangulated bowel, which was therefore returned *en masse*. Two or three weeks later the symptoms of obstruction rendered further operation necessary. There was found an omega-shaped loop of bowel adherent to the anterior abdominal wall, and with two

constrictions, the one above being especially close and hard while the intestine above it was enormously distended. An artificial opening was made above this, and three weeks later, when the distended gut had resumed its normal size, the affected loop, measuring 17 inches in length, was removed and the two ends brought together with a Murphy button. This was passed on the fifty-first day and the patient entirely recovered. Histologic examination showed the mucous lining of this upper stricture to be entirely atrophied throughout a distance of 2 c.m. (1 inch).

DR. H. O. MARCY of Boston read a paper, entitled

THE SUTURING OF WOUNDS.

He spoke first of the desirability of closing the wound permanently at the end of an operation. To do this one has to use a suture which will perfectly coapt the surfaces of the wound and at the same time is susceptible of absorption. The use of animal ligatures in wounds had for many years been employed with success before it occurred to the reader to employ such material as tendons, thus abandoning the dangerous use, in all aseptic wounds, of drainage-tubes. Catgut, however prepared, soon becomes weak and soft when buried in the tissues. Tendons have not this disadvantage, and the tendons of the cariboo and moose, and, later, the tendons of the tail of the kangaroo, have been successively tested and advocated. Of all methods of suture, the uninterrupted suture gives the best results, and each plane should be sutured by itself. An over-and-over glover's stitch is not as satisfactory as an in-and-out suture, each stitch being made to enter the tissues exactly opposite to where the last comes out, so that the thread crosses the wound at right angles.

DR. LANGLEY BROWN of West Bromwick detailed a case of traumatic aneurism of the internal maxillary artery, treated by ligature of the common carotid artery. A man, aged thirty-two, was kicked in the head by a horse, the right side of the face being badly lacerated, and the lower jaw broken in two places. The wounds suppurated and abscesses had to be opened in the face and neck. On the fifteenth day after the accident there was an aneurism in the cheek. Later, there were several dangerous hemorrhages into the mouth and neck. Two weeks later, the common carotid was tied, the aneurism subsided and recovery was complete.

MR. JORDAN LLOYD in such cases advocated the ligature of the external carotid, which is not a difficult operation.

DR. JOHN ASHHURST of Philadelphia thought that in most cases of traumatic aneurism the proper treatment is to cut down directly upon the wounded vessel, though in cases complicated by suppuration, this is a plan which has to be modified. Brain complications after ligature of the carotid are not to be feared.

THE PRESIDENT mentioned one case in which he ligated the left common carotid and, later, ascertained that the vessel on the right side was not pervious. Death resulted.

DR. THEO. A. MCGRAW of Detroit, Mich., reported
A CASE OF INVAGINATION OF THE CECUM AND VERMIFORM APPENDIX.

A boy, aged six years, was seized with an attack of cholera morbus, the stools containing, besides thin feces, only a little blood and mucus. He recovered from this attack, but while not troubled with diarrhea, constipation or with fever, he had succeeding attacks of pain, lasting from a few hours to a few days, which grew constantly more severe and frequent, until they became so severe that three-quarters of a grain of morphin was required to give relief. After a short time his condition would again be normal. Chronic appendicitis was excluded by the absence of fever, and the presence of an internal omental hernia was suspected. An incision was made above the navel, and the large intestine found inflamed, and the ascending colon had so long a mesentery that the cecum and vermiform appendix was easily brought out through the wound. The cecum and appendix were invaginated into the ascending colon, evidently a condition of long standing. A longitudinal incision was made through the constriction, and the invaginated portion drawn out and excised. The small intestine was not involved in the invagination. The patient made a good recovery.

SECTION IN OBSTETRICS AND GYNECOLOGY.

FIRST DAY—SEPTEMBER 1ST.

At 10 A.M. the President of the section, DR. WILLIAM JAPP SINCLAIR of Manchester, England, called the meeting to order and announced the postponement of the delivery of his Address until Thursday morning. DR. F. HENROTEN of Chicago then read a paper, entitled

THE OPERATION OF CHOICE IN THE SURGICAL TREATMENT OF SEPTIC PELVIC DISEASES, WITH SPECIAL REFERENCE TO THE EARLY VAGINAL INCISION.

He stated that ovarian abscess occurs much more frequently than is generally supposed. The Fallopian tubes show a smaller proportion of alterations than the ovaries which have become infected through the lymphatics, while the tube becomes secondarily diseased through contiguity of tissue. Some slight secondary changes also take place in the broad ligaments in the incipency of the affection. The diagnosis of simple uncomplicated ovarian abscess is difficult. If the woman has fever and pain, the ovary being sensitive and enlarged, slightly movable or immovable, with slight sensitiveness in the uterus, which is more or less fixed, that woman probably has an ovarian abscess. Pus forms in four or five days, and should be at once evacuated. The best route for this is through the vagina, back of the uterus. He has made 125 vaginal incisions without exsection. Pus forms in the pelvis much more rapidly than the surgeon expects, and pus in the pelvis is an exceedingly dangerous thing. Immediate incision, usually made posterior to the uterus through the vaginal fornix, with drainage, is necessary. In ninety per cent. of incipient cases of extra-uterine infection cure will follow this procedure. In old cases of pyosalpinx and in certain hyperplastic cases of tubal and uterine disease this operation will not be a success. In well-defined cases of febrile excitement and pelvic pain the early vaginal incision is indicated. He especially emphasized the importance of early incision. The most bril-

liant results follow when the operation is performed before pus forms. The objection may be made that such results will follow without operation, but recovery in these cases only follows after repeated relapses. The symptoms depend entirely upon the nature of the pus, whether infectious or non-infectious.

DR. J. ALDERSON TEMPLE of Toronto opened the discussion on

THE CAUSATION AND TREATMENT OF HYPEREMESIS GRAVIDARUM.

He stated that little progress has been made in clearing up the obscure causes of this grave disease. It is much more common in primiparæ, and much more fatal than is usually believed. Morning sickness is purely a sympathetic state, but pernicious vomiting is invariably accompanied by some pathologic condition. Carl Browne, after an experience with 105,000 obstetric cases, says he has never seen one fatal case. In the majority of fatal cases there has been an absence of reliable data regarding *post-mortem* examinations. Hossack said that in most cases we have no right to say that death results from the vomiting. Grailey Hewett lays stress on flexions and displacements of the uterus in the etiology of the disease. T. A. Emmet speaks of cervical inflammations as a cause of vomiting. Involvement of the vomiting center is claimed as a cause by many. He would urge careful discussion and further study on the subject.

DR. ARTHUR E. GILES of London has studied the cause of the vomiting of pregnancy. About thirty per cent. of pregnant women do not vomit; therefore, the vomiting must be regarded as pathologic. About fifty per cent. have no morning sickness during the first three months. When the vomiting occurs during the early months it is generally associated with hydramnios. He regards the vomiting as due to a combination of three factors: (1) exalted nervous tension, (2) peripheral irritation in the uterus, (3) an easy channel for the discharge of nervous tension through the vagus. He would divide all cases of hyperemesis into two classes: (1) those associated with organic disease; (2) those in which there is no organic disease. He does not agree with Hossack in the statement that when a *post-mortem* examination is not made the correctness of the diagnosis should be doubted. In the way of treatment he would urge arrest of the vomiting by measures which do not terminate the pregnancy.

DR. WILLIAM GARDNER of Montreal regards dilatation of the cervix as by no means devoid of danger. It may end the pregnancy, and may induce dangerous hemorrhage.

DR. R. B. MAURY of Memphis, Tenn., has seen many cases of pernicious vomiting, but has not seen many displacements associated with it, nor has he found an accompanying history of dysmenorrhea. He has treated many cases by the usual method of applying silver nitrate to the cervix, and has dilated the cervix, but has repeatedly been compelled to induce abortion, only, however, after consultation. This he regards as a serious operation. The symptoms indicating it are rapid pulse (120 or more) and dark brown or black vomit.

DR. A. J. C. SKENE of Brooklyn said that he was

taught that this disease, to begin with, is due entirely to a nervous condition. It often goes beyond this, in accordance with the rule that long-continued functional troubles will lead to organic lesions. In the ejected matter we find the products of gastritis, and he believes that this is a cause of the disease. Functional disturbance of the liver is common in pregnancy, and this may become organic, after which the stomach shares in the process. Cholesteraemia is more common in pregnancy than in uremia. He believes that Grailey Hewett is correct in ascribing the condition largely to uterine displacements. J. Marion Sims was probably the first to dilate the cervix for this condition. The speaker believes in lavage, not only in purely functional cases, but when there is hypermotility and hypersecretion of the stomach.

DR. CHARLES JEWETT of Brooklyn said that in his hands treatment has not been very satisfactory. The patient should be kept at rest and digestion coddled. Feeding by the rectum is of service. Cocain applied to the cervix uteri is valuable in many cases, especially when combined with Copeman's method of dilation to one-half or three-quarters of an inch.

MR. J. C. CAMERON of Montreal said no rule of treatment can be formulated. The patient must be treated and not the disease, which occurs irrespective of environment.

DR. ROBERT BARNES of London, through Dr. Giles, presented to the Association and the Obstetric Department of McGill University, a drawing illustrating the boundary line in placenta previa, which he designates as Bamer's boundary line.

DR. JOHN CAMPBELL of Belfast, Ireland, presented a paper, entitled

LABOR COMPLICATED WITH ABNORMALITIES OF THE CERVIX UTERI AND VAGINA.

Atresia of the cervix is best treated by scratching the site of the os and separating the membrane by a sweep of the finger. Rupture of the membrane should be delayed as long as possible. Vaginal septa may be transverse or longitudinal, and may simulate atresia of the cervix. The longitudinal septa are more common.

DR. ROBERT A. MURRAY of New York called attention to the condition of the cervix consisting in an atresia subsequent to chronic hypertrophy as a result of the application of caustics. Manual dilation is the treatment required.

DR. HOWARD A. KELLY of Baltimore said that cases of cicatricial stenosis of the vagina should not at once indicate Cæsarean section. Dilation will accomplish much.

DR. CHARLES JEWETT of Brooklyn now prefers to treat contracted cases by multiple incision and dilatation by rubber bags rather than by hand.

DR. W. C. LUSK of New York presented a contribution to the study of the first stage of labor in the form of a frozen section of a woman dying in labor from some unknown cause. He concluded: (1) that the bulging area is a retraction ring; (2) that the os internum is seen here in the first stage of labor as a distinct structure, and widely separated from the retraction ring, a lower segment

containing passive fibers intervening between the two; (3) that the contraction of the anterior fibers independently of the posterior ones, in the upper portion of the segment which meets superiorly the retraction ring, suggests a greater traction below upon the inner fibers than the outer.

DR. WILLIAM GARDNER of Montreal presented a large number of vesical calculi from a woman seventy-two years of age, who had had procidentia uteri for twenty years. The stones were removed through a vaginal incision and the woman cured.

SECTION IN PUBLIC MEDICINE.

FIRST DAY—SEPTEMBER 1ST.

The section was called to order by the President, Dr. E. P. Lachapelle, and after some preliminary business the President's address upon

THE PROGRESS OF SANITATION IN CANADA

was listened to. The reader reviewed in detail, with pardonable pride, the strides taken by sanitary medicine in the Dominion from the days of the quaint old health-laws of Louis XIV. in 1667, to the present time. The clergy at first, and until the English conquest, were the health-officers, and the parish registers the sole vital records. The system at present in force dates only from the confederation of 1867.

Next came an interesting discussion upon the question,

HOW FAR SHOULD MANDATORY MEASURES GO IN DEALING WITH (a) MEASLES; (b) WHOOPING-COUGH; (c) TUBERCULOSIS; (d) LEPROSY?

The discussion was a cosmopolitan one, but the speakers naturally adopted curiously antagonistic grounds, the English members, on the one hand, urging that persuasion should be chiefly used and legal enforcement not insisted upon until public sentiment is able to approve of it, and, on the other, the Canadian members and American participants, urging the passing of stronger laws and more stringent application of them, the difference probably being due to the fact that English communities are governed by their intelligence, ours by our ignorance, and by the time the necessity for a measure has penetrated the intellects of our legislators the whole community is thoroughly alive to its benefits.

DR. PETER H. BRICE, secretary of the Provincial Board of Health of Ontario, opened the debate. He regarded the difficulties surrounding isolation or even notification in measles and whooping-cough as extremely great. The desirability of isolation as far as possible in tuberculosis ought to be strongly urged upon the laity at every opportunity, and our most crying need is for special hospitals in every large community where such isolation can be carried out. As to leprosy, it is practically a curiosity in Canada, and demands no active attention whatever. He was not aware of more than one case of the disease in the province in which he lived.

DR. C. O. PROBT, secretary of the Ohio State Board of Health, said that measles and whooping-cough are extremely difficult to deal with legally, but they are serious factors in the death-rate, destroying more lives than scarlet fever, and should be legislated against if only to arouse

and educate the public as to the danger which may be incurred. He urged that special hospitals be provided for tuberculous patients, and that thorough disinfection, at least, of all rooms occupied by consumptives after their death be made compulsory. General sanitary measures, especially against foul air and overworking, will accomplish more than attempts to prevent communication.

DR. H. HANDFORD of Nottingham was the next speaker. He urged reliance upon persuasion and educative measures, and declared that danger lurks in legal enforcement. In all Nottingham not a single patient with scarlet fever has been forcibly removed to the isolation hospital, and yet nearly ninety-five per cent. of all such have been voluntarily taken there. Compulsion has been tried widely and has almost universally failed in England. From statistics collected by him, he believed that measles occurring during the first year of life has a mortality of nearly twenty per cent., and these patients should certainly be isolated when possible.

The subject was then opened for general discussion. DR. OLDRIGHT of Toronto favored the necessity of some compulsion, if only for educational purposes, and, with DR. E. DUNCAN of Glasgow, urged strongly that the chief danger in tuberculosis lies in infection through rooms, and that two measures should be legally insisted upon: disinfection after death, or removal and avoidance of overcrowding. Dr. Duncan reported five cases occurring in one healthy family which moved into an infected and cramped house, but could find no case of room-infection where cubic space was adequate and ventilation good. DR. CARR of Braintree, Yorkshire, and DR. A. JOHNSTON of Glasgow also urged persuasion and education, declaring that compulsory notification of measles has failed in eighty per cent. of the cities where it has been tried. DR. WOLFRED NELSON of New York commented upon the slight fear of leprosy expressed by all the speakers who had alluded to it, and declared from an experience of seven years in the West Indies and at Panama that leprosy is absolutely non-contagious, as had been voted in the session of the Pan-American Medical Congress. No case of the disease has occurred among the nurses in the Trinidad Asylum during its twenty-six years of existence, and out of 1000 cases in India, Beaven Lake found only two apparently due to contagion, and he thought sanitarians quite right in ignoring it. This evoked a spirited protest from DR. BENJ. LEE of Philadelphia and DR. F. FORMENTS of New Orleans, on the ground that they had each seen a case which was of contagious origin. This closed the discussion, and DR. JAMES T. NEECH, Health-Officer at Atherton then read a paper upon

THE PERIOD OF INFECTIOUSNESS IN SCARLET FEVER,

in which he came to the conclusion that the usual formal term of six weeks is too short, as discharged patients have proved to be the medium of fresh infection in from one to two per cent. with this limit. Apparently healthy mucous membranes seem capable of retaining infectious materials, and he urged the extension of the term of isolation to eight weeks.

DR. A. JOHNSON of the Isolation Hospital, Glasgow,

supported these positions and urged thorough disinfection of the nose and throat as well as of the skin before patients are sent home. SIR JAMES GRANT of Ottawa called attention to the bearing of this long infection period upon the possibility of puerperal infection at the hands of the physician. DR. MALCOMSON of Middleboro reported a case in which damages had actually been given against a health-officer on account of infection from a discharged patient. DR. ADAM MICKLE of Christ Church, New Zealand, also spoke briefly.

The papers of Dr. Hough of Bradford, Miss., upon "Cadaveric Fauna," and of Dr. Murray Wrotter of Washington, D. C., upon "A Report of Entomological Examinations of One Hundred and Fifty Cadavers" were of great interest. Both agreed that further investigation has failed to support the former supposed medico-legal importance of the insects present in the coffin or tissues of a corpse as to the time of burial and age since death.

REVIEWS.

DIE PATHOLOGIE UND THERAPIE DER NEURASTHENIE.

VON DR. OTTO BINSWANGER, Professor der Psychiatrie zu Jena. Jena: Gustav Fischer, 1896.

DESPITE the numerous publications on the different functional nervous disorders, any thorough investigation of this subject will be regarded as a valuable contribution to science, inasmuch as we are proceeding in this domain more or less on *terra incognita* as in comparison with organic diseases.

In view of the fact that we have to depend solely on the manifold clinical symptoms without positive knowledge of the nature of the pathologic process, it is but natural that these various disorders have been looked upon in the most diverse ways according to the standpoint of the individual observer, and that their classification has been left more or less to the discretion of different authors. While on the one hand innumerable divisions and subdivisions of functional nervous diseases have been made, there are, on the other hand, many authors who consider all these classifications as purely arbitrary and who would not look upon any of these divisions as a *morbis sui generis*, but rather as a casual complex of various symptoms.

The author of this book holds a somewhat original view in regard to the nature of neurasthenia. According to him, there is not a qualitative but rather a quantitative difference between the affection and the other functional nervous diseases, of which neurasthenia forms, so to say, the first step. "Neurasthenia stands on the borderline between the undeveloped nervous affections and the fully developed neuroses and psychoses." The following is his definition of the disease: "Under the term neurasthenia we classify all those neuropathic conditions which have developed from the soil of a general functional disease of the nervous system, but which cannot be classified among the fully developed neuroses and psychoses emanating from the same soil, on account of their unfinished character."

In accordance with this broad definition we find nearly

all symptoms of the entire psycho- and neuropathology mentioned in the book; and among the numerous cases reported we find all kinds of functional psychoses and neuroses. "Women, who kick the floor with their feet, smash plates on the floor, run up and down without purpose, and finally throw themselves on the sofa or bed crying in utmost despair" always have and probably will be called "hysterical" and not "neurasthenic," while men (case 8 and 9), who are suffering from deep mental depression with paroxysms of anxiety, and who during such an attack actually commit suicide will be considered as cases of melancholia, and not of neurasthenia.

In the same manner we find cases of hypochondriasis, of psychical degeneration, of imperative ideas, agoraphobia, topophobia, etc., described as various forms of neurasthenia. The following are the different varieties of neurasthenia according to Binswanger:

1. Neurasthenia with predominating psychical disturbances; (a) the hereditary form of neurasthenia; (b) the acquired intellectual debility; (c) the hyperalgetic form.
2. The motor form of neurasthenia; (a) with predominating irritative symptoms; (b) the parietic form.
3. The dyspeptic.
4. The angioneurotic.
5. The sexual form of neurasthenia.

While the attempt of the author to characterize and classify a special disease cannot be called a success, his book, however, will be of interest and value to anyone who seeks information about the symptomatology and treatment of general functional disorders of the nervous system.

THERAPEUTIC HINTS.

For Amenorrhea Occurring During Chlorosis.—DAUCHEZ recommends the following mixture for amenorrhea in young chlorotic girls:

℞	Syr. hypophosphite of iron	} aa	3 i
	Syr. hypophosphite of soda		
	Syr. hypophosphite of manganese		
	Glycerin		
	Cherry laurel water		m. xl.
M. Sig. Teaspoonful after meals.			

Rapid Cure for Pemphigus.—Two obstinate cases of pemphigus were cured by OHMANN-DUMESNIL (*St. Louis Med. and Surg. Journal*, June 1897), with the following prescriptions:

℞	Acidi arseniosi	.	.	.	.	gr. $\frac{1}{20}$
	Pulv. piper nig.	.	.	.	.	gr. iss
	Ext. gentianæ	.	.	.	.	q. s. ad.
M. Ft. Pil. No. j. Sig. One pill after each meal.						

The bullæ were opened, and the following ointment applied to the excoriated portions of the skin:

℞	Pulv. camphophenique	.	.	.	.	℥ i
	Ung. aquæ rosæ	.	.	.	.	℥ xvi.

To Make a Normal Salt Solution for Transfusion.—

℞	Sodii carb.	.	.	.	.	gr. xv
	Sodii chlor.	.	.	.	.	3 iss
	Aquæ	.	.	.	.	Oii.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXI. NEW YORK, SATURDAY, SEPTEMBER 11, 1897.

NO. 11.

ORIGINAL ARTICLES.

PREVENTIVE MEDICINE IN THE CITY OF NEW YORK.¹

By HERMAN M. BIGGS, M.D.,
OF NEW YORK;

PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES, NEW YORK CITY HEALTH DEPARTMENT; PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE, AND ADJUNCT PROFESSOR OF THE PRACTICE OF MEDICINE, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE conditions under which sanitary work is carried on in the United States differ considerably from those under which the sanitary authorities work in Great Britain. For instance, in the United States there is no national Board of Health, each state having its own Health Board and sanitary laws. It necessarily follows that throughout the United States there is no uniformity in regulations and methods. No definite statement can be made as to the condition of preventive medicine generally in America; but speaking broadly, in the rural districts and in the smaller towns, the sanitary methods are crude, while in many of the large cities, there is an enlightened and progressive policy to be found, equal to that in any of the great cities of the world.

The Health Department of New York City is an entirely independent sanitary organization, not being subject even to the jurisdiction of the State Board of Health. The jurisdiction of the board extends over the whole city, containing at present about 2,000,000 population, and in 1898 a similar board, increased to five members, will have jurisdiction over Greater New York, with a population of 3,250,000.

Ordinarily the duties of sanitary authorities relating to the infectious diseases are regarded as limited to the inspection of reported cases of only a few of the infectious diseases, their removal to hospitals when required, and the subsequent disinfection of the premises. In New York City *all matters connected with the scientific investigation, diagnosis, care, or sanitary supervision, in every way, of the infectious diseases are regarded by the Board of Health as properly coming within its province.*

The first important departure in New York City from the older methods was made in 1892 by the establishment of a bacteriologic laboratory, this being the first bacteriologic laboratory ever established

under municipal control. Originally designed to afford facilities for the diagnosis of Asiatic cholera, and for the investigation of questions relating to disinfection, the scope of its work was soon extended to include the bacteriologic diagnosis of diphtheria. The investigations of the New York City Health Department relating to diphtheria laid the foundation of municipal bacteriologic laboratories, and made them necessary to the proper conduct of sanitary work. In October, 1894, investigations in connection with the production of diphtheria antitoxin were begun, and in December of that year a special annual appropriation (antitoxin fund) of \$30,500 was made by the city authorities for the prosecution of this work. On January 1, 1895, the Health Department commenced the use of the antitoxin produced in its own laboratories. The special antitoxin fund made possible the establishment of a research bacteriologic laboratory devoted to the production of diphtheria antitoxin and other bacteriologic products, and to general experimental investigations in relation to the infectious diseases. In 1896 arrangements were completed for placing at the command of the physicians of New York City Widal's test for the diagnosis of typhoid fever; and recently arrangements have also been made for the administration of Pasteur's treatment for the prevention of rabies. A special laboratory and stable are devoted to the production of bovine vaccine virus, and this is freely distributed and vaccination is performed, free of charge, by the medical officers of the department.

The following statistical statement of some of the routine work performed in the laboratories of the Health Department gives a better idea perhaps of the extent of the work: During the year 1896, 25,049 cultures were examined for diphtheria bacilli; 1856 specimens of sputum from cases of suspected tuberculosis were examined for tubercle bacilli; 16,796 vials of diphtheria antitoxin were issued, and 918 patients with diphtheria were treated in their homes by the medical *attachés* of the laboratory, and 1214 persons were immunized.

Every case of contagious disease reported to the Department is inspected by the medical inspectors of the district in which it occurs, and, when necessary, such cases are removed to the Department hospitals. Disinfection is then performed, and is compulsory in every case, all infected materials being taken to the disinfection station for destruction or

¹ Abstract of the address in Public Medicine, delivered before the British Medical Association at the Sixty-fifth Annual Meeting, Montreal, August 31 to September 3, 1897.

disinfection by steam. The work of inspection is carried on by a number of different corps of inspectors. These include the district medical inspectors, the district and special vaccinators, the inspectors for the administration of diphtheria antitoxin, the diagnosticians, the summer corps of inspectors, the medical inspectors of schools, etc. There are also a number of sanitary and food inspectors, who are not necessarily medical men, such as the inspectors of plumbing and ventilation, the sanitary police, the inspectors of offensive trades, the inspectors of meat, fish, milk, etc., and the inspectors of mercantile establishments, these last having under their charge the regulations as to the employment of women and children in such establishments. Besides these, there are veterinary inspectors, who have the supervision of the application of the tuberculin test for the diagnosis of tuberculosis in cattle and the diagnosis of other infectious diseases in cattle and horses.

The method of procedure in relation to diphtheria, given in detail, is as follows:

Knowledge of the existence of cases of diphtheria reaches the Department either by a direct report of the case by the attending physician or through the forwarding of a culture to the laboratory for bacteriologic examination when the case is of doubtful character. The cases are immediately referred to the medical inspectors of the district in which the case occurred. If the person lives in a tenement, lodging-, or boarding-house, or hotel, and a culture has not been previously made by the attending physician, the inspector makes, in each instance, a culture to confirm the diagnosis. The subsequent action of the Department depends upon the result of this culture. If diphtheria bacilli are found, the case is treated as one of diphtheria; if they are absent, the subsequent treatment depends on the special conditions existing. In every instance in which the case is proven to be diphtheria, at the end of ten days a secondary culture is made by the attending physician or the district medical inspector, to determine whether the diphtheria bacilli are still present in the throat, and subsequent cultures are made at short intervals until the examinations show that the organisms are no longer present. The case is then referred for disinfection, a detailed statement being left at the house by the medical inspector in charge, to guide the disinfectors as to the course which shall be followed.

Every case of diphtheria which comes to the knowledge of the Department is recorded according to the street and number in a card index, envelopes being used in place of cards. In each envelope, representing always one case, are placed all of the data relating to the first and subsequent cultures, and

results, and as each case is recorded it is at the same time platted on sectional maps of New York City drawn to scale, showing every house lot in the city. This platting is done by conventional signs, so that it is possible at a glance to determine the grouping and distribution of cases in different parts of the city, how many cases have occurred in any given house in the city during the last four years since this method has been in use, and when the cases occurred. It is also possible in a moment, by reference to the yearly card index, to find all the information in relation to each case which the Department possesses.

A special corps of inspectors is assigned to the administration of diphtheria antitoxin, and, on request, one of these inspectors will visit a person suffering from diphtheria in any part of the city, day or night, and administer diphtheria antitoxin under the supervision of the attending physician, and in cases where the patients are too poor to have an attending physician, supervise their removal to a hospital. These inspectors are also prepared, at the request of the attending physician, to perform intubation in laryngeal diphtheria. It is the usual course, where antitoxin is administered by an inspector, to immunize all members of the family who have been exposed to the disease. Diphtheria antitoxin has also been largely employed in institutions, especially for children, when diphtheria has appeared. This is the ordinary routine, and in every instance during the last two and a half years it has been possible to quickly stamp out diphtheria in institutions by this process of immunization.

Diphtheria antitoxin is administered by the inspectors free of charge, and is furnished on request free of charge to all public institutions, and may be obtained by physicians at more than one hundred pharmacies throughout the city, where it is on sale—free of charge, for administration to persons who are too poor to pay for the remedy, the only conditions in the latter case being that reports of the cases treated be forwarded to the Health Department on their completion.

The attitude assumed by the Health Department of New York City toward pulmonary tuberculosis, and the measures adopted for its prevention, constitute a most important feature of its work. The Health Board first began an educational campaign in relation to the causation and prevention of tuberculosis in 1889, and leaflets based on a communication on this subject presented to the Board by the writer and associate pathologists, giving the essential facts as to the nature of this disease, were widely distributed. No further action was taken at that time, as investigations showed that the medical profession

and the public were not then prepared for more extended measures. In 1894, attention having been again called to the subject by the writer, it was determined to institute at once more comprehensive measures for the prevention of this disease. The measures then adopted required notification of all cases of pulmonary tuberculosis occurring in public institutions, and requested reports of cases occurring in the practice of private physicians; they included also arrangements for the bacteriologic examination of sputum, to assist in the early diagnosis of this disease; the inspection of all reported cases in tenement-houses, lodging-houses, hotels and boarding-houses, and the instruction of the patients and their families as to the nature of the disease and the means to be taken for its prevention; the inspection of the premises in all instances where deaths were reported as due to tuberculosis, and the issuing of orders, when it was deemed necessary, upon the owners of apartments which had been occupied by consumptives and vacated by death or removal, requiring that such apartment be thoroughly renovated by painting, papering or kalsomining before they were again occupied by other persons; and the education of the public, by wider and more comprehensive methods, as to the nature of tuberculosis.

Under the resolutions by virtue of which these measures were enforced, 4166 cases of tuberculosis were reported in 1894; 5818 in 1895, and 8334 in 1896. All cases reported, so far as possible, except those in private houses, were visited, and the premises where the patients lived were inspected, and, in addition, the premises occupied by persons dying from tuberculosis (numbering each year nearly 6000) were inspected, and such action taken as was considered possible and desirable. Altogether the premises and cases thus coming under observation during these three years numbered more than 35,000.

In the beginning of 1897, on the recommendation of the writer and Dr. Prudden, the Health Board of New York City finally declared pulmonary tuberculosis to be "an infectious and communicable disease, dangerous to public health," and required "the notification of all cases occurring in the city," in the same way as is required of cases of smallpox, scarlet fever, diphtheria, etc. Tuberculosis, however, is not classed with the contagious diseases, but by a special section of the Sanitary Code, enacted to provide for these measures, is referred to as "an infectious and communicable disease."

At the present time there are no hospitals directly under the control of the Health Department for the isolation of cases of pulmonary tuberculosis, but it is hoped that such hospitals may be soon provided.

Persons suffering from pulmonary tuberculosis should not be treated in association with other classes of cases in the medical wards of general hospitals, and are often very properly excluded from such hospitals. Moreover, experience has shown that in institutions devoted solely to the care of consumptives the general welfare of the patients is more easily fostered, the risks of fresh infection more certainly diminished, and the chances for recovery more surely enhanced than in general hospitals. From the beginning of this work the officials of the Health Department have encountered, in the lack of proper facilities for the care of consumptives, a great obstacle to practical success, and the writer is convinced that the grave responsibilities which rest upon sanitary authorities generally in this matter cannot be properly discharged without the establishment, under their direct control, of additional hospitals for the care and treatment of this disease. No week passes in which the officers detailed to this work in New York do not meet with many instances in which the members of many households, numerous inmates of crowded tenement-houses, employees in dusty and unventilated workshops, and many others, are dangerously exposed to infection from victims of this disease, who cannot gain admittance to the overcrowded public institutions, or who reject all proffered assistance and instruction, and, from ignorance, indifference, or inability through weakness due to the disease, scatter infectious material broadcast, and thus diminish their own chances for recovery and imperil the health and safety of others. In such cases sanitary suggestions are futile, and removal to a hospital constitutes the only effective action.

The Health Department of New York City, while feeling strongly that the most important source of infection is through the dried sputum of consumptives, has elaborated with great care methods for protecting the public, as far as is within its power, from infection by the meat and milk of tubercular animals. Since 1895 no milk has been allowed to be sold within the city without a permit from the Health Department, and before these permits are issued information must be furnished as to the source from which the milk is obtained, the number of animals, the character of the food-supply, and the sanitary conditions surrounding the dairy. There are also special regulations controlling the sale of milk, and the permits may be revoked if these regulations are not complied with. All milch cows in the city are subjected to the tuberculin test, and animals found to be diseased are killed. There also exists a careful inspection of animals slaughtered for food and of all meats sent into the city, and the carcasses of those found to be tubercular are destroyed.

Another amendment to the Sanitary Code which has recently been enacted, as the result of investigation by the Department showing that the dust of street-cars and various public places is often infectious, prohibits the spitting on the floors of cars, ferry-boats, etc., and requires that all companies post notices to this effect in the public conveyances.

Most beneficial effects have already resulted from the various measures instituted for the prevention of tuberculosis. Not only has there been a very material decline in the number of deaths occurring from this disease, but there has been a most gratifying increase of knowledge and intelligence among the poorest class of the population as to its nature. This increase of intelligence, and the precautions resulting from it, afford the greatest promise in the future of a persistent and still more rapid decline in the frightful mortality caused by the tubercular diseases.

The method employed for recording and platting cases of diphtheria has also been used for cases of tuberculosis. Transcripts from the maps on which are platted the cases of diphtheria and tuberculosis have been prepared, to show the distribution of those cases in certain wards of the city. Thus from an analysis of the distribution of reported cases and deaths from tuberculosis in Wards 4 and 6 of New York City, for the years 1894, 1895, 1896 to March, 1897, it appears that during this period only thirty-eight per cent. of the inhabited houses of these two wards were infected with this disease, and that fifty per cent. of the cases of tuberculosis occurred in twenty-three per cent. of the infected houses, these constituting only nine per cent. of all the dwelling-houses in the wards. The facts, as shown by a study of these maps, argue more forcibly for the infectious and communicable character of this disease than could any words.

Early in 1897, under the authority of a special resolution of the Board of Estimate, 150 medical school inspectors were appointed, and a system of medical school inspection was begun. During three months, sixty-five school days, in which this system has been in operation, there have been examined 63,812 children, and 4183 were excluded from school for the following diseases: Measles, diphtheria, scarlet fever, croup, whooping-cough, mumps, contagious eye diseases, parasitic diseases of the head and body, chicken-pox, and skin diseases. This system of school inspection has thus far given most satisfactory results and promises still more for the future.

The educational work of the Health Department constitutes a very important feature of its usefulness. It has been the custom of the Department for some years past to issue from time to time circulars of in-

formation on various topics, and especially those connected with infectious diseases—their diagnosis, treatment, or management. Some of these circulars are popular in character, very large editions being published, 50,000 or more at a time, and are designed for general distribution, particularly among the tenement-house population. These circulars are published by the various medical journals and by the daily papers in New York City, and thus gain a very wide circulation. They are also sent by mail or delivered by messenger to the physicians of the city. Aside from the circulars described, numerous scientific bulletins have been issued from the bacteriologic laboratories, detailing the results of original investigations in connection with infectious diseases, and these bulletins are widely distributed among the profession of New York City. The importance of this educational work cannot be overestimated. Its value is incalculable in disseminating popular and scientific information in regard to the results of the latest studies in infectious diseases, and there have been constantly exhibited in New York the most gratifying indications of the influence of the information thus distributed, on both the general public and the medical profession. More than this, the circulars keep constantly before the medical profession and the laity the work, the duties, and the functions of the Health Department, as related to the people and the profession. The criticism has often been made, particularly in Europe, and in the earlier work of the New York City Health Department, that the methods proposed were impracticable. The results have shown that they are not impracticable. What has been described is not something that it is proposed to do, but it is a statement of what has been done, and the work, as briefly outlined in some of its phases, is to be considered as only introductory. It is the purpose of the Health Board to establish a supervision of all infectious diseases along the lines which have been thus far developed, in relation to tuberculosis and diphtheria, as rapidly as the scientific knowledge at command will make such a course possible.

The final test of the efficiency of any scheme of sanitary control and of the healthfulness of any locality is found in the mortality statistics, considered in relation to the causes of disease and death. Various factors and conditions, however, may influence these, such as density of population, nationality of the inhabitants, and physical conformation of the country. The conditions in New York City are in many respects very unfavorable. The average density of population of the larger part of New York, that is on Manhattan Island, is greater than that of any other great city of the world. Sanitary District A

of Ward 11, New York City, has a population of more than 800 to the acre; Ward 10, over 640 to the acre; Ward 13, 540; Ward 17, 430. The only localities approaching these wards in density of population is a small area in Paris, where the population is 430 to the acre; one district in Prague with 485 to the acre, and the Whitechapel district in London, which has a population of about 300 to the acre in Spitalfields, Mile End, and Newtown, and 365 in Bethnal Green. The density and cosmopolitan character of the population of New York also renders the sanitary problems presented extremely difficult of solution. Then, too, the physical conformation of Manhattan Island, which is long and very narrow, produces overcrowding, fully three-fourths of the population living in tenement-houses, which are five, six, or more stories high, and contain from two to four or more families on each floor.

These facts should be kept in mind in considering the mortality statistics of New York, as compared with those of the large cities of Great Britain and the Continent. With them before us, the diminution in the death-rates, and the present death-rate, are most significant.

A comparison of the mean death-rate for decennial periods in New York City since 1834 shows that there was an increase during the first three periods ending in 1863, and that since that date there has been a continuous and very heavy decline in the rate, especially marked in the most recent years. The mortality in New York arose to such a point that the inhabitants became alarmed, and in 1866 the Health Department as now constituted was organized. In the decennial period ending in 1843 the mean death-rate was 28.03; for the period ending 1853 it rose to 33.81; the next period, ending in 1863, it was 33.94. Since that time it has declined to 31.11 for the decennial period ending in 1873; to 26.87 for the period ending in 1883; to 25.78 for the period ending in 1893, while in the year 1894 it was 22.76; in 1895, 23.10; in 1896, 21.54, and for the first half of 1897, 19.60. The population meanwhile has increased from 312,000 in 1840 to an estimated population of 1,990,000 on July 1, 1897. The mortality-rate is normally higher for the first half of the year than the second half, and it is, therefore, probable that the rate for 1897 will be a fraction over 19, or a diminution of twenty-five per cent. on the death-rate for the decennial period ending in 1893.

The search for the causes of diminished mortality from all causes shows that the largest reduction has been in the zymotic death-rate, including diarrheal diseases of children under five years, and there has been also a steady and important decline in the

tubercular death-rate since 1886. Investigation further shows that a special reduction in the mortality from diphtheria and croup, amounting to nearly forty per cent., has occurred since the introduction of diphtheria antitoxin with the beginning of 1895. This reduction has taken place in spite of an increase in the number of reported cases of this disease. Up to the beginning of 1895 there had been a steady increase for some years in the mortality from diphtheria and croup, and for the year 1894 the death-rate was higher than that from any other single disease, excepting tuberculosis and pneumonia—pneumonia really including a number of different affections. The combined death-rate from measles, scarlet fever, diphtheria, croup, smallpox, and typhoid fever has been reduced exactly one-half within ten years, the rate for 1896 for these diseases being 1.64 per 1000 population, as contrasted with 3.26 for 1887; for 1897 it will apparently be still lower.

The government of the United States is democratic, but the sanitary measures adopted are sometimes autocratic, and the functions performed by sanitary authorities paternal in character. We are prepared, when necessary, to introduce and enforce, and the people are ready to accept, measures which might seem radical and arbitrary, if they were not plainly designed for the public good, and evidently beneficent in their effects. Even among the most ignorant of our foreign-born population few or no indications of opposition or resentment are exhibited to the exercise of arbitrary power in sanitary matters. The public press will approve, the people are prepared to support and the courts sustain, any intelligent procedures which are evidently directed to the preservation of the public health. The belief is never aroused in any class of the population, however ignorant, that the institution or enforcement of any sanitary measure is primarily designed for the restriction of the individual freedom. There is nowhere to be found any jealousy or distrust of law or government, as such. It is therefore possible to adopt measures more arbitrary in many respects than could be adopted in most other countries, simply because our government is democratic. This gives the keynote to the attitude of the sanitary authorities of New York.

It may be truly said that there is no great city in the world to-day which, in the broad sense, is cleaner and healthier than New York. By clean is meant the purity of the atmosphere, the cleanliness of the streets, the abundance and purity of the water-supply, and the efficiency of the sewerage system. No city is healthier, considering all the sanitary factors in the situation, such as the size and density of population, the varied nationality of the inhab-

itants, the character of the climate, etc. Nowhere can there be found a fuller recognition than in the United States of England's high standard of excellence in public medicine, or a more sincere appreciation of her vast contributions to the progress of sanitary science. But she must look well to her laurels if her cities are to be kept cleaner than the great cities of the United States, or her urban population is to be healthier and happier than the same class on this side of the Atlantic.

THE TREATMENT OF CONVERGENT STRABISMUS IN CHILDREN.¹

By L. A. W. ALLEMAN, M.D.,
OF BROOKLYN, N. Y.

IN general, our definite knowledge of a medical subject is inversely as the contributions to its elucidation. This, unfortunately, applies to strabismus, for despite the thought and patient observation which have been devoted to this matter, it is still true, as has been said by Dr. Chas. Stedman Bull, that "the whole subject of strabismus is the least understood by modern ophthalmologists in the whole domain of ophthalmic science." I hasten, therefore, to assure you that I shall not still further obscure the subject by the statement of theories or by the discussion of the mooted points, but shall simply outline the method of treatment which experience has demonstrated to be most effectual in these cases. The discussion will not include paralytic conditions in which the power of excursion of an eye in certain directions is diminished or abolished through paralysis of an ocular muscle. I will concern myself only with concomitant strabismus. Here the associated movements of the eyes are performed with little or no limitation of motion, but the observed object is fixed with one eye only, the other maintaining in all directions a relative position of too great convergence.

The association of convergent strabismus with hypermetropia was pointed out and explained by Donders, who demonstrated the normal relations of convergence and accommodation, showing that for a certain position of convergence we naturally put forth a corresponding accommodative effort, and that in hypermetropia a correction of the optical defect is obtained by an effort of accommodation proportionately greater than that made by a normal eye, and in excess of the convergent effort required for the same distance. Hence, a hypermetropic subject must learn either to dissociate the two functions or to sacrifice either distinctness of vision or binocular single vision. Should one eye chance through op-

tical defect or disease to have much poorer vision than its fellow, the choice is easily made, and strabismus results, diplopia being avoided by mental suppression of the image of the more defective eye. While this theory fails to explain all the cases of strabismus, and while we find instances in which hypermetropic eyes with markedly unequal vision do not squint, it may, for our present purpose, be assumed as sufficient, especially as the treatment which it suggests is attended by a gratifying measure of success.

In some few cases strabismus develops very early in life and binocular fixation is never acquired, but as a rule it is first seen when the child begins to observe its surroundings in a manner requiring more prolonged and accurate fixation, that is, during the third or fourth year. It is sometimes alternating, either eye fixing indifferently, and usually is periodic, being at first only momentarily present, when the child is tired or excited, and reappearing more and more frequently, and finally becoming permanent in one eye. At the first appearance of the squint the advice of the family physician is often sought, and this is my excuse for bringing the subject before you. It is sometimes urged that popular opinions on medical subjects are the result of observations of generations of the laity, and have a sound basis of fact somewhere; but for the very general belief that squint, if left to itself, will be relieved spontaneously, there is small foundation, and I think that the structure of expectation is built largely on the dread of the surgeon's knife.

I will not deny that squint sometimes does disappear of itself, but the correction is more often cosmetic than actual; the eyes have straightened sufficiently to relieve the deformity, yet binocular single vision is not established, and in these cases the patient often experiences more annoyance than in others in which the deformity is more noticeable. I therefore strongly advise against leaving these cases to themselves on the chance of improvement, and will briefly point out the lines of treatment most likely to relieve the condition.

The non-operative treatment of strabismus may be summarized as relieving accommodative strain. No one rule can be given for the accomplishment of this result, and each case will present its own peculiar requirements; the treatment, therefore, must be modified by expediency. Children differ so widely in their mental development and tractability that no arbitrary age can be fixed, but as to treatment, I will divide the cases into two general classes as to when they can or cannot be given glasses.

In the first class there are certain patients who from birth or shortly after have shown a permanent

¹ Read at the Thirteenth Annual Meeting of the Fifth District Branch of the New York State Medical Association, held at Brooklyn, May 25, 1897.

squint of marked degree. (This must not be confounded with the wandering of the eyes of young infants before binocular fixation has been acquired.) Such cases are proper ones for early operation, as they are likely to prove troublesome at best, and it is important, if possible, to give the eyes a correct position during the development of the visual apparatus, thus enabling the patient to learn to use them properly. Delay in remedying the deformity often permits an eccentric portion of one retina to become functionally connected with the macula of the straight eye (the so-called second macula), which, when the squint is corrected later on, gives double vision in the proper position, and adds to the difficulty of effecting a cure.

A word may be said here as to the amblyopia of squinting eyes. In many cases of strabismus the visual acuity of the squinting eye is found to be much lower than that of its fellow. In some cases the reason is apparent in an opacity of the cornea or lens, in some intra-ocular disease, or in an error of refraction; in others there is no discoverable abnormality. On careful examination these eyes will show frequently a blind spot (central scotoma) at the macula, sometimes only for color, and often very small and difficult to detect. Two explanations have been offered of this condition: One, that the eye deteriorates through non-use, as the psychical suppression of the macular image is habitual (amblyopia exanopsia), the other that the defect is primary and the *cause* of the squint.

It probably is true that the habitual suppression of the image of one eye during the period of development does prevent its acquiring full visual acuity, and amblyopic eyes frequently do improve greatly in vision under a correcting glass, proper position, and exercise. It is also undoubtedly true that in many instances some anatomic defect is present, due, possibly to a small macular hemorrhage at birth or to some other cause which we cannot detect by means of the ophthalmoscope. In such cases no amount of use will develop perfect vision. While we cannot educate away structural defects, even these eyes will occasionally improve somewhat with use, and if the fellow eye has normal vision the patient will suffer no apparent inconvenience. Another reason for the early correction of the deformity is the unfortunate influence it exerts on the mental growth of the child. The consciousness of being different, and the heartless criticism of its playmates, tend much to the development of self-consciousness, and entails a great amount of needless suffering on a sensitive nature.

While operation is indicated in the above-mentioned cases, I do not advise it, as a general rule, until I am satisfied that a cure cannot be obtained by

hygienic measures. For very young children (those two or three years of age) who are just developing squint, very careful supervision is necessary. It should be impressed upon their parents that the eyes should have as little near work as possible, and they should be made to understand that this excludes other things than books and pictures. It is astounding, when one looks into the matter, that so little harm results from the toys which are ordinarily given to children. Many of the common toys found in the shops require as accurate vision in their use as the reading of very fine type, and it is the least robust children who most enjoy such toys. The sound, hearty child cannot, from the very excess of its animal spirits, stick to any one thing long enough to do itself much harm. We must exclude from the nursery, then, all picture-books, blocks, segmented toys, kindergarten games, sewing, and whatever requires vision at short range, substituting large toys and, above all else, out-of-door exercise, as much country as possible, with its opportunities for exercising vision at long range, and its restful tones of color.

Careful attention to the bodily health is indispensable. When, under such a regimen, the squint persists, it is well to bandage the fixing eye for a time each day and to compel the child to use the squinting eye, if there be vision enough to enable it to move about. To this may be added the occasional use of atropin, either in both eyes, or in the better eye alone, to force the squinting eye into use. In this way we can carry these children along to an age when glasses can be worn. In many cases this is surprisingly early, sometimes before the third year.

With the second class of children—those who can wear glasses—the first step is to put them under atropin. The result is often marked and immediate, and we can form a fairly accurate idea of the outcome of treatment by the behavior of the eyes under the influence of the drug. When the squint is at once corrected by it, it is safe to predict a cure by the use of glasses. When there is little or no improvement, or when the squint is increased, the cure will be less prompt; but even in these cases, if the parents can be induced to persevere, it may be effected. A year or more may be required, and the effort may for a long time seem to be entirely unavailing. Improvement will be usually manifested at first by an occasional return to a correct position, which will be more and more frequently attained. Sometimes this is quite rapid when once begun.

An accurate measurement of the eyes of young children for glasses is difficult, but by the ophthalmometer of Javal and the ophthalmoscope we can obtain fairly satisfactory results, which can be improved from time to time as the child grows older.

Glasses are usually readily accepted by children, for the relief of the accommodative strain is appreciated by them and they will tolerate quite full corrections.

If the squint is not relieved by the use of atropin and glasses, exclusion of the fixing eye should be practised, and atropin may also be used at intervals if it produces a good result. Systematic exercise with the stereoscope is of great advantage, and the pictures adapted to the use of children are valuable. Attention to the general physical welfare of course is all-important, and a careful regulation of the kind and amount of near work should be observed. This does not mean that these children should be kept from school, but that they should be permitted to do their work under proper conditions. In our private schools these matters already have received much attention, and I believe that the conditions of light, ventilation, etc., are generally excellent. In the public schools they are no doubt as good as they can be made with the means at the disposal of the authorities.

In our own homes there is a very great opportunity for improvement. How often do we find in our houses any provision for the comfort of the children during their study or reading? They must make the best shift they can with the arrangements provided for the adult members of the family. If we were compelled to habitually use chairs and tables suitable for a race twice our size, we would complain bitterly, but this is practically what we demand of our children. It is a simple matter to provide a higher chair or a lower table, for ordinary furniture may easily be adapted to their use. An adjustable rack for holding a book properly is not a great luxury, and any one of ordinary mechanic skill can easily improvise one. I need not urge the importance of these aids to correct posture; we need only put in evidence the drooped shoulders of almost every man we meet who has led a studious life to prove the contention that the matter is one deserving of careful attention.

Artificial light for reading should also be looked into. We frequently find on inquiry that a child is working by an exposed gas-jet, high over its head. Such a light is barbarous; it is insufficient and flickering, is in a bad position, and is little better than the tallow-dip of our fathers. A student-lamp is probably the best readily obtainable source of artificial light, as it fulfils fairly well all the requirements of color, brilliancy, and steadiness. It is shaded, and is low enough to prevent the bright image of the flame from striking directly on the retina.

I cannot here go more fully into these questions of general ocular hygiene; they are, in my judgment, very important matters, not only in squint cases, but

also in the prophylaxis of myopia. The effort of the physician should be to prevent rather than to cure disease, and when the laity, through a better understanding of physical processes, are able to grasp this truth, and will take the trouble to find out how properly to care for their eyes and the eyes of their children, our endeavors to ameliorate by surgical methods the results of neglect will no longer be necessary.

In the majority of cases of strabismus, the treatment thus indicated will, I am sure, prove successful, yet there are some in which, after a patient trial, we fail utterly to obtain a good result, or in which, for some reason peculiar to the case, we wish to avoid delay. In such, operation will be indicated. If possible, the operation should be performed under cocain anesthesia. With most children, however, this is impracticable, for though we can render the procedure painless, we cannot without force keep a young patient reasonably still, and therefore must resort to ether.

In operating, I always aim at an under-correction of the defect. The immediate result is not so brilliant, but the after-result is better. This is particularly true of children whose orbits are near together, for as the face develops and the orbits diverge, the consequent change in the relative position of the eyes may convert an immediately successful result into an over-correction. This danger, however, is reduced to a minimum by the modern operation of tenotomy. It is not unusual to find a disfiguring over-correction from the older operation of myotomy, but after a tenotomy this is rarely seen. A relative insufficiency, however, may result from a too free division of the interni. I will not discuss the technic of the operation, nor the relative advantages of tenotomy and advancement. Whatever the operative procedure is, the aim should be the establishment of binocular fixation, as well as removal of the deformity, and the patient should not be dismissed as cured until we can demonstrate by the use of the stereoscope that this object has been attained.

PRESSURE NEURITIS CAUSED DURING SURGICAL OPERATIONS.

By HOWELL T. PERSHING, M.D.,
OF DENVER, COL.;

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE UNIVERSITY OF DENVER.

WITHIN the past two years my surgical colleagues have referred to me a number of cases of painful, localized paralysis, which first had been noticed immediately after recovery from anesthesia. As this totally unexpected sequel of operation has always been disheartening to the patient and annoying to

the surgeon I wish to call attention to the possibility of its occurrence, and to the necessity of taking certain simple precautions which will prevent it. In all the cases except two, the paralysis was in one arm. The following will serve as an example:

N. H., male, aged thirty-four years, general health good. Nine days before examination he was operated upon for varicocele, under ether. Immediately after recovering consciousness he discovered that his left arm was numb, heavy, and weak. Since then the arm has been useless, and a stinging numbness has been felt which delays his going to sleep at night, but only rarely is severe enough to wake him after he has once fallen asleep. All the joints of the arm can be moved, but only feebly and with difficulty. Movements of the shoulder and elbow are as weak as those of the wrist and fingers. Inability to raise the arm (paralysis of the deltoid) or to place it behind the trunk (paralysis of the latissimus dorsi) is especially annoying on account of the interference with the act of dressing. The faradic reactions are retained, and there is no wasting or other trophic symptoms.

Here, the whole brachial plexus was evidently damaged at the time of operation, and there can be no doubt that it was due to the arm having hung over the edge of the table so that the nerve trunks were subjected to pressure, probably for some time. In the other cases I have seen, the explanation of the condition has been the same. The recent introduction of narrow operating-tables, with sharp edges, and the scant covering for the table which is often deemed sufficient, seems to me to have greatly increased the liability of the occurrence of this accident; nevertheless, I have not seen this cause mentioned in the literature of neuritis.

In the foregoing case the prognosis is good. The absence of complete paralysis, severe pain, and change in the electric reactions makes it highly probable that in a few weeks the arm will have recovered. But not all cases of this kind are so favorable, although ultimate recovery is nearly always to be expected. A young woman who, after a comparatively trifling gynecologic operation, suffered in the same way, but who had severe pain, glossy edema, and some loss of faradic irritability, did not recover full use of her arm for several months.

The operating-table used at one of my operations had an edge which was raised above the general surface. The patient, a woman in poor general health, lay in such a position that the left knee rested on this edge. The external popliteal nerve undoubtedly was compressed against the fibula, for immediately after recovery from the anesthesia, she complained of the usual numb, stinging pain in the area comprised in the distribution of this nerve, and there was well-marked foot-drop. The anterior tibial and peroneal

groups of muscles wasted, lost faradic irritability, and gave the reaction of degeneration to the galvanic current. Ultimate recovery ensued, but at the end of two months, when the patient left Denver, it was still incomplete. In another case the pressure of Clover's crutch caused neuritis of the external popliteal, which fortunately subsided after a few weeks.

Little need be said of the means of preventing such unfortunate accidents when attention has been called to the possibility of their occurrence. The patient's arms should not be allowed to hang down, and care should be taken that during operation the weight of the body is as evenly distributed as possible. Keeping the patient in any constrained position should be avoided when not absolutely necessary, and the use of any mechanic contrivance for maintaining a desired position should be with due care to prevent nerves from being stretched or pressed upon. If neuritis does occur, the first indication is to secure absolute rest of the affected part during the early stage. At this time voluntary motion, massage, electricity, or any other excitant of muscle and nerve will do harm. When the pain and tenderness have subsided, counter-irritation, gentle rubbing, and the galvanic current may be used to advantage. The faradic current often is harmful, and is useless except as a means of diagnosis or as a counter-irritant applied to the skin.

CLINICAL MEMORANDA.

A CASE OF SARCOMA OF THE LUNG, WITH SYMPTOMS OF ADDISON'S DISEASE FROM INVOLVEMENT OF THE SUPRARENAL CAPSULES.¹

By FREDERICK A. PACKARD, M.D.,
OF PHILADELPHIA;

VISITING PHYSICIAN TO THE PHILADELPHIA AND CHILDREN'S HOSPITALS, AND TO THE OUT-PATIENT DEPARTMENT OF THE PENNSYLVANIA HOSPITAL; INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA;

AND

J. DUTTON STEELE, M.D.,
OF PHILADELPHIA;

ASSOCIATE IN THE PEPPER CLINICAL LABORATORY; ASSISTANT DEMONSTRATOR OF MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA.

CLINICAL REPORT BY DR. PACKARD.

THE case herewith reported is placed on record partly because of the rather infrequent occurrence of such massive malignant disease of the lung, partly because of the rarity of bronzing of the skin from carcinomatous and sarcomatous involvement of the suprarenal capsules. During life the diagnosis was made of primary malignant neoplasm of the lung, with secondary deposit in and destruction of the adrenals, and it was only after careful consideration of the pathologic conditions found at au-

¹ Read before the College of Physicians of Philadelphia, April 7, 1897.

topsy, and a histologic study that the word "primary" was omitted from our title.

The patient was a man, aged thirty-three years, who was admitted to the Philadelphia Hospital, July 1, 1896, suffering from cough and hemoptysis, which dated from December, 1895. He was a native of Holland, a day laborer by occupation.

When first seen in October, 1896, when I went on duty at the hospital, I was much impressed by his peculiar facies. His face expressed much suffering, his skin was of a peculiar sepia color, his mucous membranes were exceedingly pale, and his sclera of a remarkably blue color.

His father died at the age of fifty-three years of "dropsy;" his mother, three brothers, and a sister, are alive and well. All of his family are said to be of a dark color. He had the ordinary diseases of childhood, but was never seriously ill until the onset of his present trouble, and always considered himself a healthy man. He never used alcohol immoderately, never contracted venereal disease, and had received no injury.

His present illness dated from December 23, 1895, although he had had a hacking cough for some time before. On the date mentioned it was noticed by his landlady that there was some blood in his expectoration, although he himself had not noticed it at this or at any prior time. Soon after this he noticed pain in his right side, a new symptom in his trouble. These symptoms—cough, hemoptysis, and pain in the right side of the chest—had continued with increasing severity until the time of examination. In February, 1896, he began to have severe pain in the right leg, especially in the knee. This pain continued with great intensity until his death. Careful and repeated questioning failed to elicit any history of increasing darkness of skin, and the patient frequently declared that his skin always had been dark.

Early in October the following notes of his condition were made: "He is thin to emaciation. The attitude when sitting on a chair is constrained, the weight being thrown to the left side, the hands being held on the arms of the chair in order to overcome the jar produced by coughing. When in bed the decubitus is on the right side, with the right thigh and leg strongly flexed. The slightest movement of the trunk or right leg causes excruciating pain, so that without an anesthetic thorough examination of the right hip is impossible. The breathing is hurried, shallow, and frequently interrupted by a smothered cough. The radial pulse is equal on the two sides, rapid, and compressible. The face is drawn and sad, the skin of the face light olive or sepia in hue, the upper eyelids very dark. The mucous membrane of the mouth is very pallid and shows no area of pigmentation. The sclerae are very blue, the pupils equal and natural. The right side of the neck is decidedly fuller than the left, from the presence of two or more enlarged supraclavicular glands.

"The skin of the trunk is very dark. On the front of the chest on the right side are two darker areas, an inch and a half square, said to be the result of two blisters that were applied six weeks ago. The pigmentation in these areas is very decided, not being produced by

the hyperemia and pinkish discoloration ordinarily seen after the use of blisters, but of a dark-brown color. Over the right half of the thorax at the base there is a larger but rather less deeply pigmented square area which marks the site of a mustard plaster applied one or two weeks ago. (These areas remained of the same or possibly of a darker color until the time of the patient's death.) The areolæ of the nipples are very dark, and there is a slight increase of pigmentation in the axillæ.

"The thorax is long, the downward curve of the ribs being very marked. The costosternal angle is very acute. On both sides the clavicles stand out prominently, from sinking of the upper portion of the chest. The right side moves but little during respiration; the left shows rather exaggerated respiratory excursion. The heart is in the normal position; the area of cardiac dullness is unaltered from the normal, so far as can be determined, and the heart-sounds are clear and free from murmurs. Over the right chest anteriorly the percussion-note is absolutely flat, with great increase of resistance to the percussed finger. This flatness and increase in resistance is possibly more marked above the fourth rib than below that point. The dividing lines between the toneless note over the lung and that due to the heart and liver cannot be determined, although a slight difference in the pitch at the upper border of the seventh rib on the right perpendicular nipple line would seem to indicate the upper border of the hepatic area. The liver dullness extends downward to the costal margin. The percussion-note over the left lung anteriorly is exaggerated except immediately below the left clavicle, where it is impaired. The area of splenic dullness is normal. Over the right side anteriorly there is absolute silence on auscultation save in the infraclavicular region, where there is distinct cavernous breathing over a small area. Vocal resonance and tactile fremitus are absent, except over the area of cavernous breathing, where there is poorly developed bronchophony.

"Posteriorly the examination shows a decided deviation of the thoracic spine to the left, and marked pigmentation over the sacrum. The right lung posteriorly and in the axillary region is dull, almost to flatness, with great increase of resistance, showing absence of breath-sounds except near the root, where there is distinct bronchial breathing, with numerous moist râles. Over the left lung there is exaggerated resonance, with puerile breathing.

"The abdomen is scaphoid, but is otherwise negative, there being no marked increase of pigment beyond that of the whole surface of the body. No tumor-mass can be felt. The external genitals are very dark. Examination of the right knee shows merely slight fulness on each side of the patellar tendon, there being no floating of the patella, and, so far as can be determined, no abnormal range of movement. The right leg shows no other abnormality, but careful examination of the hip cannot be made without an anesthetic, owing to the great pain caused by the slightest manipulation."

The urine, save for a high specific gravity (1025) was normal. Examination of the eye-grounds was negative except for a high degree of choroidal pigmentation, possibly not excessive for a man with normally rather dark-

coloring and black hair. Laryngeal examination was entirely negative. Examination of the blood showed simple anemia with equal moderate reduction of the red cells and hemoglobin, and no leucocytosis.

The sputum was somewhat peculiar in that it was tough, apt to be expectorated in clumps, and was of a peculiar white color. It was on one or two occasions slightly streaked with blood, but at no time had the currant-jelly appearance or grass-green color. No fragments of growth could be found in it, the only peculiar fact noted being that there was much amorphous, granular material, and detritus in addition to a small number of pus-corpuscles. (The examination of sections of the lung shows clearly why tumor-tissue could not be recognized in the broken-down granular material which probably composed the greater part of the expectoration.) Tubercle bacilli were never found during repeated examinations.

During the entire time of his hospital life the patient had a very irregular temperature, with constant evening exacerbations of from 1.5° to 2° F. It attained 102° F. in the evening on a few occasions, but the average evening temperature was $101\frac{2}{3}^{\circ}$ to $102\frac{2}{3}^{\circ}$ F. That of the morning was from $97\frac{2}{3}^{\circ}$ to $99\frac{2}{3}^{\circ}$ F. The pulse was uniformly rapid, being constantly above 105 to the minute.

The appetite was poor, the bowels usually regular, but at times moved too frequently. Some sweating at night was present at times, but it was not excessive, and it was not out of proportion to his debility.

The conditions noted above persisted until the time of his death, with the exception of the physical signs over the right lung. At each examination after that first made there was constantly absolute dulness, with complete silence over the whole right lung. The abnormal pigmentation noted in areas on the chest slowly but continuously became darker until death. About a week before death the feet and legs became swollen to a marked degree, the edema being soft and deeply pitting. During the last twenty-four hours of his life the breathing was of the Cheyne-Stokes' type. Immediately before death internal strabismus was present, but of which eye is not stated in the notes. Death occurred, apparently from asthenia, on November 13, 1896.

The diagnosis made during life was primary tumor of the right lung, with secondary involvement of the adrenals. The only other condition seriously considered was inflammatory thickening of the pleura from tuberculous infection, with concomitant fibrocaseous change in the adrenals. The negative result of the sputum, it was thought, might have resulted from loss of function of the right lung from compression by the thickened pleura and consequent absence of expectoration from the diseased lung; but further observation demonstrated that the amount of sputum was too great to be accounted for by the slight physical signs on the left side of the thorax. The constant absence of tubercle bacilli from the expectoration, in spite of repeated careful examinations, allowed but three lesions to be considered as possible causes for the physical signs present in the right side of the chest—primary endothelioma of the pleura, tumor of the lung itself, and non-tuberculous thickening of the pleura. The

latter was excluded by absence of retraction of the right half of the thorax, by the previous history of the case and the course of the disease, by the presence of an enlarged lymph-node above the right clavicle, and by the involvement of the adrenals. The history of quite early hemoptysis pointed to tumor of the pulmonary parenchyma rather than to endothelioma of the pleura.

As has been said above, careful examination of the right hip and thigh was impracticable without anesthesia, on account of pain, and the condition of the patient did not warrant either causing pain or administering an anesthetic. Owing to the apparently normal condition of the bones on superficial and hasty examination, the possible bony origin of sarcoma, with secondary pulmonary and suprarenal involvement, was not considered in making the clinical diagnosis. It might be added that after the patient's death, as his body was being turned on the back, the right femur suddenly snapped at its upper portion. It is, therefore, on the whole, well that thorough manipulation and handling of the thigh and hip for diagnostic purposes was not attempted during life.

PATHOLOGIC REPORT BY DR. STEELE.

Autopsy held at the Philadelphia Hospital seven hours after death.

There is a considerable increase of pigmentation on the face, hands, and genitalia, though not marked upon the hands. The scrotum is of a light sepia color. There is no discoloration of the mucous membranes. Dark hair and dark eyes. There is a scar behind the great trochanter of the femur, which is sharply and distinctly pigmented and is of a dirty-brown color.

Abdominal Cavity.—There is a hard mass in the head of the pancreas, about the size of an English walnut, which, however, is not adherent to any of the surrounding structures. The mesenteric glands are slightly enlarged, but do not seem to be affected by the new growth. In other respects the relations of the abdominal cavity are normal. The liver extends to the fourth interspace above, 2.5 cm. below the costal margin in the midclavicular line and 9.5 cm. in the median line.

Heart.—Relaxed. The ventricles are distended by hard, white coagula. The myocardium is pale and somewhat fatty. The valves and endocardium are normal.

Pericardium.—Normal.

Pleura.—The two layers are tightly adherent over the whole of the upper and middle lobes of the right lung. When traction is made upon the adhesions the visceral layer of the pleura separates from the lung over an area of degeneration in the middle lobe. In one place the cavity formed by the softening has ruptured into the pleural sac. The degeneration is evidently due to a new growth. The pleural sac upon this side contains 300 cubic centimeters of a blood-stained fluid, in which are floating masses of degenerated tumor-tissue which somewhat resemble blood-clots. The left pleura is free from disease.

Lungs.—The right lung upon examination is seen to be extensively infiltrated by the tumor-mass. The entire middle lobe and the lower half of the upper lobe are de-

generated and cystic. The pleura is thickened over the affected areas and studded with hard, white nodules. Similar nodules are seen in the lung-tissue around the edges of the degenerated areas. The upper part of the lower lobe is somewhat infiltrated, and is exceedingly congested throughout.

The left lung is normal. The bronchial lymphatic glands at the root of the right lung are much infiltrated.

Spleen.—Measures 11 x 12.5 x 2.5 cm. The organ is softer than normal. The pulp is semifluid and easily removed. There is a hard, white nodule about the center of the organ. The center of the nodule is slightly hemorrhagic.

Suprarenal Capsules are both much enlarged, the right especially so. Both capsules are studded by dense, white nodules which in some places are commencing to soften in the center. They vary in size from five to ten millimeters in diameter. There is an especially large nodule at the apex of the right capsule which appears to be hemorrhagic. To the naked eye there does not seem to be any remains of the normal tissue of the capsules.

Kidneys are normal in size. The capsules strip readily. The pyramids and medullary rays are congested. In one of the central pyramids of the left kidney is a hard, white nodule measuring three millimeters in diameter. The cortex on both sides is of the normal width and presents nothing of interest.

Ureters, Bladder, Rectum, Duodenum, and Stomach are normal.

Pancreas.—Thickly studded with nodules, especially at the head. Some of these are hard and white, while several show areas of softening in the center. The common bile-duct is surrounded by new growth. This apparently compresses it, but does not infiltrate its wall.

Thyroid Gland.—Normal.

Supraclavicular Lymph-Glands are enlarged, but do not seem to be involved by the new growth.

Semilunar Ganglia.—Of usual size and appearance; not involved by the tumor.

Intestines.—Normal.

Liver.—Uniformly and deeply congested. There are several white nodules upon the upper peritoneal surface of the right lobe which average eight millimeters in diameter. There are a few nodules scattered through the substance of the same lobe. There are irregular areas of a yellow color, evidently of a fatty change, scattered through the liver. The gall-bladder is distended by viscid bile and contains two semi-inspissated masses, which are dark-green in color and easily broken down. The common and cystic ducts are distended, but not markedly dilated. They average three millimeters in diameter.

Skeleton.—In the substance of the skull, in the parietal bone of the left side, is a round nodule, yellow in color and more transparent than the rest of the calvarium. On section this is found to lie in the diploe, is softened in the center, and resembles a new growth. It is one centimeter in diameter. The external table is pressed outward over this area.

The shaft of the femur on the left side, just below the anatomic neck, is much degenerated and breaks upon ex-

amination. The cause of the softening is evidently a focus of the same tumor-tissue seen elsewhere in the body. The whole shaft of the bone for eight centimeters below the anatomic neck is involved. The epiphysis is not affected. The growth shows much degeneration, and the softened material has formed a sac about the affected bone.

Brain.—Membranes normal. There is a recent apoplexy in the left crus cerebri, which has broken into the fourth ventricle. The clot is red and soft and perfectly homogeneous, and does not suggest a neoplasm. It is limited to the fourth ventricle and the crus.

Microscopic Examination.—A portion of the femur was decalcified, and the sections stained by hematoxylin and eosin. The tissue is in such an advanced stage of degeneration that it is the exception to find an area in which the nuclei take the stain. There is considerable osteitis and resorption of bone, and the only traces of the original structure of the part are scattered areas of bone-tissue. The sections contain much connective tissue, which appears to represent the periosteum. This tissue is hyperplastic, as shown by the number of round cells which it contains. In some areas there are alveoli which are packed by cells of a great variety of shapes. Some are large, round cells, with vesicular nuclei; others are spindle-shaped, with oval nuclei; others are small and lymphoid in character. An occasional giant-cell is found. In many places the nuclei have ceased to stain. The cells are degenerated, and are rounded and indefinite in outline. In many fields nothing can be seen but granular debris. The arterioles of the part show some thickening of the intima.

No sections were cut from the growth in the skull. Sections taken from the thickened visceral pleura show much round-celled infiltration and hyperplasia of the connective tissue. In places the collections of round cells are so considerable as to suggest sarcomatous tissue. The arterioles are thickened and surrounded by bands of connective tissue, but the areas of greatest inflammation lie around the lymph-channels. These vessels are much dilated, their walls are thickened, and they are surrounded by much round-celled infiltration. Their endothelial lining is thickened, and the lumen is packed by desquamated cells, between which there is a considerable amount of pigment. The endothelial cells are seen only in the lumen of the channels, and have not infiltrated the tissues. In nest-like spaces in the proliferating connective tissue are collections of polymorphous cells similar in the three main types to those of the growth in the femur. Giant-cells are rather more numerous. There is much degeneration of the nuclei of the polymorphous cells. Some show a condition of karyolysis with fragmentation of the chromatin; in others the nuclei are vacuolated, and in others there is hyperchromatosis, with lumping of the chromatin.

The nodules in the pleura and lung are found to consist entirely of cells of the most varied shapes, but which follow in general the three main types which are found in the other organs. There are also a few giant-cells, perhaps three or four in each microscopic field. The lymphatics are somewhat dilated and contain pigment, but

desquamation of the epithelium is not a prominent feature, though present in some places.

We have considered the significance of the dilatation of the lymph-channels and the desquamation of the endothelium found within them, and think that the condition is not one of new growth within the vessels, but a lymphangitis, probably caused by dilatation of the network of the lymph-vessels of the visceral pleura, produced by obstruction to the lymph-stream by the new growth. In support of this view is the fact that the evidences of inflammation of the pleura are much more marked around the lymph-radicals than around the smaller branches of the pulmonary artery.

The pancreas shows many nodules, consisting of the polymorphous cells described in the lung and femur. The degenerative changes in the chromatin are not as advanced as in the places already described. Here, also, giant-cells are found in moderate numbers. The small nodules in the liver consist of collections of cells similar to those described. Giant-cells are present.

In the right suprarenal capsule the tubules of the cortex show much degeneration. Many of the nuclei are fragmented and the cells are desquamated and granular. The connective tissue of the gland is hyperplastic and surrounds the tubules with dense bands of fibrous tissue. The nodule, described as softened and hemorrhagic, is found to be a focus of the tumor growth, similar to those described elsewhere. Into the mass there has been a profuse hemorrhage which has pushed aside the cells in a remarkable manner. There is very little fibrin present, and the red cells retain their outline unchanged. We consider, therefore, that the hemorrhage occurred but a very short time before death.

In the left capsule the cells of the gland are somewhat degenerated, and there is a slight hyperplasia of the fibrous tissue, but the changes are not as advanced as on the right side. The nodules scattered through both organs are found to be foci of sarcomatous cells, as described in the other organs. We estimate, however, that about one-quarter of each gland is unaffected by the tumor. The semilunar ganglia and nerves of the solar plexus were not involved in the growth, and on microscopic examination show nothing abnormal.

The skin shows many pigment granules which lie in and between the cells of the corium, but are very little, if at all, in excess of those found in the normal skin.

The pathologic diagnosis seems to us to be clearly that of a giant-cell sarcoma of the mixed type. The question of the primary seat of the growth has been most perplexing. The fact that but one lung is affected would suggest that the process might have originated in the lung; but we have concluded that it was primary in the femur for the following reasons:

1. It is a mixed sarcoma. The tumors of this class arising from the periosteum are usually of this type, while those originating in the lung are oftener of the small, round-cell variety.

2. Giant-cells are present in all of the sections. While these cells are not exclusively confined to sarcomata of bone, they are much more common in this locality.

3. The advanced condition of degeneration in the femur suggests that the tumor had been growing there for a longer time than in the lung, for the reason that such a condition would cause more rapid breaking-down in the softer tissues of the lung.

The sequence of events seem to us probably to be as follows:

1. Primary involvement of the periosteum of the femur.
2. Secondary growth in the lung, with extensive degeneration.
3. Metastases through the degenerated efferent pulmonary vessels to the left heart, and through the arterial circulation to the various organs.

The cerebral hemorrhage, from its small extent and from the evident freshness of the coagulum, seems to us to have occurred in the agonic period.

NOTES ON THE OPERATIVE TREATMENT OF COMPLETE VAGINAL AND UTERINE PROLAPSE; WITH REPORTS OF TWO CASES.¹

BY FREDERICK HOLME WIGGIN, M.D.,
OF NEW YORK;
VISITING GYNECOLOGIST TO THE NEW YORK CITY AND
ST. ELIZABETH'S HOSPITALS.

THERE are few ills if any that womankind is subject to, other than malignant disease, which produce greater disability and discomfort than procidentia of the uterus, or, when the uterus has been removed, of the vaginal wall, accompanied as it is in the first instance by chronic inflammatory changes of the organ and, in either case, by the displacement of both bladder and rectum, with marked interference of their functions, this often being followed by cystitis and proctitis. The condition under consideration is that of a reducible hernia through the pelvic floor, and, as is well known, the most frequent cause of the difficulty is an unrepaired rupture of the perineum and an inability on the patient's part to confine herself to bed for a proper length of time after the birth of her child, thus causing a strain on the relaxed ligaments by the enlarged and heavy uterus. Therefore, it may be said that we have first a damaged perineum, accompanied by constipation, then a rectocele, then a cystocele, and finally the gradual escape of the uterus from the body. The sign of the disease is a local tumor, and the chief symptoms are backache, bearing-down pains, difficult and painful micturition and more or less inability to walk.

The patient on coming under our control should be placed in bed, and the parts reduced and held in position by tampons previously moistened with boroglycerid solution, attention being paid to the intestinal canal and bladder. The mechanic devices for the relief of the condition are numerous; the best may be said to be Gehrung's pessary and Braun's colpeurynter, but in the writer's opinion, the treatment, in a majority of instances, should be in the line of restoration of the damaged parts to their normal condition. If the patient is seen before the uterus has de-

¹ Read at the Thirteenth Annual Meeting of the Fifth District Branch of the New York State Medical Association, Brooklyn, May 25, 1897, and before the Waterbury Medical Association, June 14, 1897.

scended very far, an operation on the posterior and anterior walls may suffice, but when the prolapse is complete, additional means must be employed if we would permanently retain the displaced parts in their proper place; and it is the especial object of this paper to call attention to two of the more recent procedures that have been devised to enable us to accomplish this purpose, *viz.*, those of Baldy and Fritsch. In connection with this subject a report of the following cases will prove of interest:

CASE I.—On October 23, 1896, A. M., a widow, thirty-eight years of age, was admitted to the gynecologic service of the City Hospital. She said that she first menstruated during her fifteenth year, that the periods had been regular, and that the flow had ceased after the performance of an operation at another hospital about a year before. She had never miscarried, but had borne three children, sustaining an injury, due to the use of instruments, at her first confinement, which took place about eleven years prior to her admission. It was for the relief of this condition which, from the patient's description, appeared to be due to prolapse of the uterus, that the operation previously alluded to was undertaken. She also said that she was unable to retain her urine. On examination, a mass about six inches in length and four inches broad was found protruding from the vulva. The tumor proved to be the inverted vagina containing intestine and bladder, the latter holding twenty ounces of residual urine. The mucous surface of the vagina was dry but not ulcerated. The cervix was absent, but in its place there was a scar which showed that a vaginal hysterectomy had previously been performed.

On November 2d, after the patient had been prepared in the usual manner and anesthetized, the peritoneal cavity was opened by an incision in the abdominal wall to the left of the linea alba, and after the ovaries had been removed and the adhesions connecting the intestines to the vaginal sac broken up, the sac having been replaced and being held up by an assistant, the patient lying in the Trendelenburg posture, the vagina was attached to the remaining portions of the round and broad ligaments on each side by means of heavy silk sutures. The wound in the abdominal wall was then closed and ordinary dressings applied. The patient next was placed in the lithotomy position and an area two inches in diameter on the anterior vaginal wall was denuded of its mucous membrane. Beginning in the center of the denuded area and working from above downward tier-sutures of chromicized catgut were inserted, which caused the cystocele to disappear, a ridge of enfolded tissue being left along the anterior vaginal wall. The cut edges of the mucous lining of the vagina were then brought together by means of a purse-string suture of heavy silk after the method of Stoltz. Attention was next paid to the posterior vaginal wall and perineum. The flap-splitting method of Tait was employed, the dissection, however, being carried well up to the crest of the rectocele. After this had been accomplished, the parts were brought together by means of buried sutures of silkworm gut.

Convalescence was uneventful, with the exception of slight stitch-infection at two points in the abdominal wall.

On November 26th the patient was out of bed and about the ward, and her local condition was in every respect satisfactory. During April, six months after the operation, she was examined by the writer who found her perfectly well, she having regained full control of the bladder.

CASE II.—On November 17, 1896, M. R., a widow, sixty-six years of age, was admitted to the gynecologic service of the City Hospital. Menstruation had first occurred during her fifteenth year and had continued at regular intervals until her fiftieth; it was painless and of the monthly type. She had borne four children. There was no history of a miscarriage. She had enjoyed good health until about three years before when she had been knocked down and trampled upon by a horse, the animal planting its forefeet upon her abdomen. Soon after this occurrence she noticed that a tumor, which gradually increased in size, projected from the vaginal orifice. She had suffered from prolonged constipation, sometimes not having a bowel movement for sixteen days. This condition was usually followed by diarrhea. She also had been troubled with incontinence of urine.

Examination revealed the presence of a tumor about five inches in length which projected from the vagina, giving to the vulva the appearance of elephantiasis. At the apex of the tumor there were several points of ulceration. The condition was diagnosed as one of complete uterine prolapse. As the patient was very feeble and anemic, and the urine was of low specific gravity and contained albumin, pus, and casts, it was decided that operative measures should be deferred. After a thorough cleansing of the inverted vaginal surface and ulcerated cervix with a solution of hydrogen dioxid, the parts were replaced and retained by means of cotton tampons previously soaked in a boroglycerid solution, which were removed and replaced from time to time. The bladder was catheterized every eight hours, and washed out with a boric-acid solution, and the bowels gradually unloaded by means of enemata and repeated small doses of calomel continued for several days at a time. Later, tonics, especially iron and strychnin, were given. Under this treatment the patient's general and local condition gradually improved, and during January, 1897, as she was anxious to be up and about, and as various futile attempts had been made to hold the parts in place by means of pessaries, it was decided to make an effort toward affording her permanent relief. As her general condition was such that the induction of general anesthesia was unwise, it was determined to rely on other means for the relief of pain during the operation, the method devised by Fritsch being the one best suited to the case. The patient's age made the obliteration of the vaginal canal unimportant.

On January 18th, after a hypodermatic injection of one-third of a grain of morphin had been administered, and she had been properly prepared, the cervix was seized with bullet-forceps and drawn down, and a small quantity of a weak cocaine solution injected under the mucous lining of the vagina. A buried suture of silkworm gut was then carried around the vagina a little above the cervix and the latter was pushed up. The suture, the ends of which

emerged from the same opening, was then drawn tight, tied, and the ends cut off short, causing the knot to disappear from view, and to be buried in the tissues. This procedure was repeated until six similar sutures had been placed, encircling the vagina at various points, which resulted in an entire obliteration of the prolapsed tissue and of a greater portion of the caliber of the canal. The perineum was split according to Tait's method, and the cut surfaces drawn together by means of several sutures of silkworm gut. During the operation the patient hardly complained of pain, and there was little or no evidence of shock. On January 25th the perineal sutures were removed, and convalescence was uneventful. On January 30th, twelve days after the operation, she was up and about the ward. She was seen by the writer during April, and her local condition found to be satisfactory. Her general condition also was much improved as she had regained control of both bladder and rectum.

The chief points of interest in the first case are, first, the procidentia of the vaginal wall following vaginal hysterectomy, which apparently had been undertaken for the relief of uterine prolapse. This condition, however, more frequently follows the removal of the uterus by the technic ordinarily employed, whether by the vaginal or abdominal route, than is generally supposed. In the second place, the laparotomy undertaken for the purpose of breaking up the intestinal adhesions and of attaching the replaced vaginal walls to the stumps of the broad and round ligaments near the pelvic brim on each side, prior to the performance of the operations on the vaginal walls, is worthy of note. This procedure is in line with Baldy's suggestion contained in an article, entitled "A New Operation for Uterine Prolapse," published in the April, 1896, number of the *American Journal of Obstetrics and Diseases of Women and Children*. He advises that in performing an abdominal hysterectomy, after amputating the organ at the internal os, the remaining tissue should be attached to the stumps of the broad ligaments on each side. The writer believes that this procedure is a good one, and that it should be employed in many cases of procidentia. For a number of years past he has endeavored to prevent the occurrence of a hernia of the vaginal walls following his operations for the removal of the uterus, for whatever cause, either by the abdominal or vaginal route, by closing the wound in the vaginal wall after attaching said wall to the stumps of the round ligaments. Another point of interest was the combined operation on the anterior wall.

The second case is of interest mainly because of the fact that it was possible to do all that was necessary for the patient's relief, notwithstanding her poor condition and inability to take a general anesthetic, with little or no pain, and that no unpleasant symptoms resulted from the procedure. It is also interesting to note that the permanent buried sutures in the vaginal wall, while retaining it in a good position, did not give rise to discomfort. This case would appear to demonstrate the fact that no matter how old or feeble a patient may be, or how bad her local condition, the case should not be considered hopeless, nor should the patient be allowed to remain a suffering, bedridden invalid.

THERAPEUTIC NOTES.

Radical Cure of Epithelioma.—*The Med. Week* of June 11, 1897, contains an article on the above subject by CERNY AND TRUNECEK. The preparation employed by them is a mixture of arsenious acid with alcohol and water, as follows:

R	Powdered arsenious acid	.	.	.	1 part
	Ethyl alcohol	{	aa	.	75 parts.
	Distilled water				

The directions are to clean the ulcer thoroughly, although a few drops of blood are essential to the action of the remedy. The mixture is shaken, and applied with a brush. No dressing is needed. The arsenic mummifies the tissues and forms a crust, which grows thicker from day to day, as fresh applications of the mixture are painted over it. After the first crust comes away, the ulcerated surface is again painted, as at first. If on the following day there is the commencement of a new crust, the applications must be continued daily until this crust also comes away. If, however, on the following day there is only a thin, easily detached pellicle, then the cancerous elements are destroyed and the ulcer may be allowed to heal.

In the course of treatment, as the crust becomes thicker, the strength of the application may be increased with advantage from 1 to 150, at which treatment is begun, to 1 to 100, or even 1 to 80. To avoid contractions, the edges of the ulcer, when this is allowed to heal, are daily rubbed with boracic-acid ointment.

The writers report three cases of epithelioma of the nose cured in the manner described. One of the tumors was recurrent, one patient refused operation, and the other was refused operation on the ground that the growth was too far advanced for removal. Treatment lasted about three months, and the periods of freedom from recurrence have lasted now from six months to more than a year. Several other cases were treated without success, but in no instance were the directions faithfully carried out.

Combinations of Mercury for Subcutaneous Injection.—

R	Calomel	.	.	.	.	gr. xxiv
	Sterilized olive oil	.	.	.	.	$\frac{3}{4}$ i.

M. Sig. Fifteen minims to be injected once a week. This mixture should be sterilized at a temperature of less than 100° C. (212° F.)—*Fournier*.

R	Binioid of mercury	.	.	.	.	gr. iv
	Sterilized olive oil	.	.	.	.	$\frac{3}{4}$ ii.

M. Sig. Inject 15 to 30 minims every three or four days.—*De Lavarenne*.

R	Cyanate of mercury	.	.	.	.	gr. x
	Sterilized water	.	.	.	.	$\frac{3}{4}$ ii.

M. Sig. For intravenous injection, 15 minims; for subcutaneous injection, 25 minims.—*Abadie*.

A Skin Lotion.—DUHRING recommends the following preparation as a mild stimulating lotion for the skin:

R	Zinci sulphat.	{	aa	.	.	3 ss
	Potassii sulphuret					
	Spt. vini rect.	.	.	.	.	$\frac{3}{4}$ iii
	Aq. rosæ	.	.	.	.	$\frac{3}{4}$ iii ss.

M. Sig. To be diluted, as required, for external use.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished in place of other remuneration. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscripts should be typewritten.

SATURDAY, SEPTEMBER 11, 1897.

THE ABUSE OF MEDICAL CHARITY.

THE matter of indiscriminate abuse of medical charity at nearly all of the dispensaries of this city is of such paramount importance to all who have the welfare of the younger members of the profession at heart that it calls for immediate and decisive correction. It has been claimed that at least three out of five of the eight hundred thousand patients treated free of charge at the dispensaries during the year 1896 were able to pay at least a moderate fee for the services rendered, and the correctness of these apparently incredible figures being granted, the question naturally arises as to with whom the blame for this condition of affairs lies. It is a characteristic of human nature to obtain as much as one can for as little expenditure of time, energy, or money, and, this being the case, the item of medical services is no exception to the rule. From a strictly moral standpoint, then, at the door of this class of patients must be laid the censure; but should it not equally be directed toward those who not only permit but encourage the evil? The question can be answered only in the affirmative.

Many excuses for the present dispensary system

have been made, and when all have been given careful consideration the fact still remains glaringly evident that to the almost complete lack of systematic investigation as to the merit of an applicant is to be attributed the present unpardonable condition of affairs. Underlying this apathy, or purposeful negligence, it would seem, are three factors, to one of which one must look for an explanation of the cause. These are (1) a desire to show in the annual report of the dispensary a great array of figures which will convey to an admiring public an adequate idea of the great and beneficent work being done; (2) in those dispensaries connected with teaching institutions, the desire to preserve a sufficiently large *clientèle* to assure for the students a varied assortment of clinical material; (3) the praiseworthy effort to furnish to those young physicians who have not had the benefit of hospital training subsequent to graduation an opportunity to obtain experience which, later, will fit them for the supposedly extensive and diversified exactions of private practice.

Concerning two of these factors but little need be said. When it is remembered that at the so-called teaching dispensaries, perhaps one patient in twenty applying for treatment is brought before a class of students, and that this patient in a majority of instances belongs to the unfortunate poor contingent for which the free dispensary originally was designed, and which, sooner or later, inevitably finds its way there, this argument will be seen to be untenable. As for the young physician being catered to and regarded with fatherly solicitude by the governing boards of dispensaries, things medical surely have reached a most millennium-like pass if this is to be accepted as true, but, unfortunately, it is not. But in spite of this, the fact remains that the budding practitioner does lay in a store of valuable knowledge which will stand him in good stead during his professional life, and without which he is distinctly inferior to the more fortunate ones who are armed with the strength of a hospital experience. But is it at all necessary to open wide the dispensary doors to all comers, irrespective of social state or worthiness, in order that this knowledge may be gained? Can it not be obtained through the medium of that worthy class in which disease is sufficiently rampant to encourage the physician, be he young or old, to bend his every effort toward its alleviation? The

economic side of the subject also must be taken into consideration, for, when this same young physician attempts to build up the lucrative private practice of which he has dreamed, will he not find that the dispensary to whose success, in the eyes of the public, he has contributed is a rival too strong to be downed?

In the absence of these two factors it would seem that the one first mentioned must be responsible for the evil as it exists to-day, and the mainspring of this condition can be nothing less than a desire for personal aggrandizement.

It has been claimed repeatedly that the amount of medical charity abuse has been grossly exaggerated by those who are making an honest effort to reform it. The report of the special committee appointed by the Medical Society of the County of New York to investigate this subject should be accepted as conclusive in this respect.¹ The concluding paragraph of that report reads as follows:

"In conclusion, your committee expresses the conviction that there is no species of charity so beneficent, so far-reaching, or so generously bestowed as true medical charity, and that nothing could be further removed from its wish than that it should be curtailed or kept from the reach of the deserving poor; but it has been so conclusively demonstrated that there exists such gross and unpardonable abuse of that charity on the part of those who are not entitled to it that it has become imperative to adopt radical measures for the suppression of that abuse, and at once."

In order to carry out measures of reform in this as well as every other matter so vital to the public weal, practical unanimity of action is necessary, and this appears to be impossible in the present instance except under the guidance of a fair and honest law which, in the end, will confer benefit upon both the physician and the deserving applicant for his gratuitous care.

MRS. GRUNDY'S STRAIT-JACKET.

MUCH has been written in condemnation of the corset-wearing habit, but the probabilities are that many more reams of paper will be filled by eminent medical authority before a full realization is obtained of the manifold evils which follow in its train. The effect of the corset is obtained not only by preventing the wings of the lower chest and sides from expanding in inspiration, thus compelling the dia-

phragm to drive the viscera directly downward, but also by cramping and preventing the contraction of the wall-muscles, causing the anterior abdominal wall to bulge out and distend below, until the tone of the recti is destroyed. In this the corset, of course, is ably assisted by the drag of the heavy skirts usually worn and the consequent crippling of the movements of the lower limbs due to their Laocoon-like folds. Moreover, as Stockton has pointed out, these displacements seldom or never occur before adolescence, when corsets are first applied, and, with that rare philosophic breadth of view reaching far beyond the limits of his own specialty, and typified by his persistent contention that the cause of a very large number of the disorders of the stomach lies entirely outside of the organ itself, this observer declares that in his experience not only are a great number of gastro-intestinal diseases dependent upon displacements of the viscera, due to loss of tone in the abdominal muscles, but that much of the "backache" and dragging-down sensation, so common in women, are of identical origin. The commonest factor in their causation is prolapse of the colon, kidney, or stomach, instead of the uterus, as has been popularly supposed.

But the most serious charge against this garment has been made latest of all. The extraordinary predilection of chlorosis and the simple anemias for the female sex, and especially during the ten years following puberty, has long been a puzzle to clinicians. Light was thrown upon the question by the statements of Sir Andrew Clark and Carpenter, when they asserted that it depends upon constipation and the absorption of putrefactive products from the food-canal—a "stercoremia," as the former called it; but the problem still remained, Why does constipation begin so suddenly and universally at this age-period? Now, however, Glenard comes forward with the bold statement that a large majority of cases of chlorosis are toxemias due to ptoses of the food-canal, and the time of first wearing the corset is the period most fruitful in them. His position has been sustained and even extended by Sigaud in France, Meinert in Germany, and Stockton in this country. Meinert has made an especially elaborate study of the subject, and asserts that chlorosis is a secondary anemia and the direct result of enteroptosis produced by improper clothing during the developmental period in

¹ See THE MEDICAL NEWS, May 29, 1897.

girls. The result of treatment directed to the ptoses strikingly corroborates this theory.

In view of these facts, one is justified in urging the profession to yet another onslaught upon this modern Moloch. Nor will mere condemnation and destructive criticism suffice. We must be prepared to suggest a substitute. The skirt must be greatly lightened, shortened (if possible, divided), and strictly limited to the purpose of an external decorative drapery, with no reference whatever to warmth. Petticoats should be entirely abolished, or at least reduced to a single one of silk or light flannel, and warmth and protection of the lower half of the body secured *entirely* by means of close-fitting drawers ("tights"), stockings, and bloomers. All garments must be supported from the shoulders, either by direct continuation, waists, or broad and elastic suspenders. The superiority of the Venus-de-Medici waist over the "Redfern" monstrosity, and of the grace of movement and elasticity over dead rigidity of outline must be insisted upon, and the love of beauty called to our aid. Every convention or habit, either of dress or behavior, which interferes with free play and development of all the muscles of the abdomen and chest-walls must be swept away.

The odds against us are heavy, but we have a new and powerful ally just now in the shape of the bicycle. As a writer in these columns remarked some months ago, the wheel "has already effected a breach in the rampart against which the profession and the pulpit have been thundering in vain." The heavy, crippling, and back-breaking skirt is going; may we not hope that the corset will be the next to follow?

ECHOES AND NEWS.

Medical Journals of Paris.—There are 120 medical journals published in Paris.

The Royal Victoria Hospital, Belfast.—The sum of \$500,000 has been raised to found a new hospital in Belfast in commemoration of the Queen's Jubilee.

Appropriation for a Bacteriologic Laboratory.—The Legislature of the State of New Jersey has granted an appropriation of \$3000 to the Bacteriologic Laboratory at Princeton.

Professor Koch and the Rinderpest.—It is reported that Professor Koch will return to South Africa in order to make further investigations and experiments in regard to rinderpest.

Typhoid Fever in Dawson City.—The news comes from St. Michaels, Alaska, that typhoid fever is epidemic among the miners at Dawson City, and that several deaths from the disease have occurred.

Beef from Cows Killed by Lightning.—A man was recently held in the Liverpool, England, city police-court for exposing for sale the carcasses of cows which had been killed by lightning. The meat was unfit for human food.

Premium for Twins.—A Brooklyn, N. Y., landlord offers a house and lot rent free to the first family among his tenants to whom twins are born. To the first family to whom triplets are born he will present a house and lot.

Inspection of Chinese Laundries.—An inspection of Chinese laundries has been ordered by the Health Commissioner of St. Louis, Mo., who fears that some may mouth-spray their work with tubercle bacilli and thus spread contagion.

Gold Medal for Professor Kolliker.—Professor Kolliker of Wurzburg has been awarded the Gold Comenius Medal by the Imperial Leopold-Carolina Academy of German Scientists of Halle, in commemoration of his eightieth birthday and jubilee of his appointment as professor.

Bellevue Hospital Medical College's New Building.—Plans for the new building of the Bellevue Hospital Medical College have been filed with the Building Department. It is to be erected on the corner of First avenue and Twenty-sixth street, adjoining the Carnegie Laboratory, and is to cost \$95,000.

Cerebral Hemorrhage and Wheeling.—A Syracuse, N. Y., woman, while making a run on her bicycle last week, was riding rapidly with her companions, when she suddenly threw her hands to her head and uttered a sharp cry. When lifted from her wheel life was extinct. A necropsy showed a ruptured vessel at the base of the brain.

To Care for Sick Plants.—In Berlin the Institute fur Pflanzen Physiologie und Pflanzen Schutz gives, without charge, advice and information regarding diseases and injuries of cultivated plants. It will also send agents to examine plants without charge beyond the railway ticket, which, in some instances, will be paid for by the institute.

Death of Dr. Cornelius Kollock.—The death is announced of Dr. Cornelius Kollock at his home in Cheraw, South Carolina, on August 17th. Dr. Kollock was graduated from the University of Pennsylvania just after the War and then went to Europe, where he studied under Velpeau. He was one of the most eminent physicians in the South and an authority on abdominal surgery.

Suspicious Death of the Late Shah's Physician.—It is reported in Paris that the death of Sir Joseph Tholozan, physician to the late Shah of Persia, was due to poison. For thirty years he was the trusted confidant of Nasr-ed-Din and it is supposed that his knowledge of court secrets made his removal desirable. He was a native of France and seventy-seven years of age at the time of his

death. His predecessor at the Court of the Shah also was poisoned, it is said.

The Record Broken.—What appears to be an authentic case of a woman who has given birth to four pairs of twins has been reported in St. Louis, Mo. The woman in question, who is only eighteen years of age, has lived in East St. Louis during the past five years and recently applied to Dr. Woods, Supervisor of the Poor, for food for herself and children, of whom all but three are dead. Dr. Woods carefully investigated the statements of the woman and found them correct.

Origin of the Bombay Plague.—It is generally believed that the plague was imported into Bombay from China via Singapore. However, Dr. Hutcheson, Sanitary Commissioner of the Northwest Provinces, thinks that it comes from the mountain region of Gurhwal, 3000 feet above the level of the sea, where it makes its appearance every year and is nurtured and perpetuated amid the filth which accumulates under and around the dwellings of the ignorant people who inhabit these otherwise healthy altitudes.

Roentgen Rays Made Harmless.—From time to time since the use of skiagraphy became general in medical and surgical practice unexpected effects have been observed to follow its application in a limited number of instances. That this malign influence upon the tissue is not a constant or necessary quality of the ray is evident from the fact that its disastrous results only occasionally appear. Without being able to offer a theoretic analysis of the problem Mr. Elliott Woods of Washington, D. C., has made the practical suggestion that a film of gold foil properly prepared will arrest the undesirable elements in the field of radiation.

The Leprosy Congress at Berlin.—Twenty-one papers on subjects of debatable interest will be read by invitation at the Leprosy Congress to be held at Berlin October 11th to 16th, next. Among them may be mentioned those of Professor Koch, on "The Place of Leprosy among the Infections;" of Professor Virchow, on "The Pathological Anatomy of Leprosy;" of Dr. Unna, on "The Histology of Leprosy;" of Professor Neisser, on "The Extent to which the Bacillus Lepræ Should Be Regarded as the Cause of the Disease;" of Professor Campana, on "The Cultivation of the Bacillus of Leprosy," and of Professor Besnier, on "The Value of Heredity and Transmissibility as Etiologic Factors."

Persecuting Chinese Laundrymen.—An enterprising proprietor of several laundries in the upper part of New York City has been circulating what purports to be a notice from the Board of Health warning people of the prevalence of leprosy in the Chinese quarter of the city. The circular is really an abstract from the report of the Board of Health for 1891, in which one of the health commissioners made mention of leprosy among the Chinese residents of New York. The object in casting it broadcast is evidently to deter people from patronizing Chinese laundrymen and in this way to increase the business of the afore-

said enterprising proprietor. The attention of the Chinese minister has been called to the matter, and he has already written to the Board of Health to ask for an explanation.

Sanitation and the Death-rate.—The last report of the Health Board of New York City shows an encouraging decrease in the mortality-rate, especially from diarrheal diseases. Even those districts whose inhabitants are most inimical to the exercise of sanitary laws show that great improvement has followed the enforced cleaning of streets and the regular removal of garbage. The condemnation and abandonment of tenement-houses which have heretofore successfully resisted the promulgation of the proper principles of ventilation and decent existence will even further improve the statistics. The Board of Health should always have encouraging support and popular appreciation of its laudable efforts.

"The Christian" and Matters Medical.—In his latest contribution to fiction Mr. Hall Caine has indulged in certain assertions which must strike his medical readers with consternation at the ruthless manner with which he brushes aside the time-honored principles underlying their science. Thus, when she is further unnecessary to his plot he staggers pharmacology by removing a flighty female with "half a grain of liquor strychnin." Medico-legal traditions are not less abruptly overturned in his description of a still-born child as "one that has breathed but never cried." In what a state of dismay must the plodding man of science await the further revelations of this rising genius.

Tuberculosis in a State Institution.—The Board of Regents of the State Agricultural College of Kansas has discovered that the domestic animals at the college farm are not only infected with tuberculosis but that the disease has been communicated to many of the attendants in charge. In at least three of those who reside on the farm the infection has brought them to Death's door. In view of the serious nature of affairs an order will be given for a general slaughter of the cattle at an early date, with provisions for *post-mortem* examinations. That such a state of affairs should be allowed to develop in an institution devoted to the teaching of scientific farming must bring humiliating reflections upon its sponsors.

The Private Madhouses of England.—Mr. George Russell, Under Secretary of State for the Home Department in the Roseberry administration, has inaugurated a movement calling for the abolition of private madhouses and will ask Parliament to take vigorous action to this end. He asserts that while in office he had exceptional facilities for studying the subject of private lunatic asylums, that they constitute the greatest iniquity in England, and announces that he will produce before the House revelations of the most startling character. Mr. Russell declares that a man should have no more right to keep a private asylum than a private prison; that the alleged inspection of such of these asylums, as are known, is a mere farce, and that the most incredible cruelties are perpetrated behind their walls.

Yellow Fever in Mississippi.—A well-authenticated report has just been received of the appearance of yellow fever on the coast of Mississippi, at a watering-place known as Ocean Springs. Suspicious cases have been observed during the last fortnight and as death has occurred in several instances, the character of the malady has been so well established that the Health Officers of the neighboring states have published the information and ordered rigid quarantine measures against the unfortunate resorts. At least one person, in whom the disease proved fatal, had returned to New Orleans before its nature was suspected, and many sensational reports of deaths in other places have been promulgated. It is safe to predict that most of these will not merit credence when carefully investigated. The Health Boards of Mississippi and Louisiana, as well as that of New Orleans, assert confidence in their ability to control the present outbreak. The source of the infection is not yet clearly established, but the quarantine station at Ship Island has been in close communication with Ocean Springs, and is naturally suspected, as vessels from subtropical countries where yellow fever is endemic constantly touch at this point for government inspection.

CORRESPONDENCE.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

[From our Special Correspondent.]

THE TRIP TO MOSCOW—ENTHUSIASM OVER RUSSIAN HOSPITALITY—PERFECT ARRANGEMENTS FOR THE MEETING—THE FIRST GENERAL SESSION.

MOSCOW, August 20, 1897.

THE Twelfth International Medical Congress has been inaugurated under most favorable circumstances, and the general impression conveyed to the minds of those who have come so far to attend it is exceedingly satisfactory. Despite the immense number of travelers which the Russian railroads, unused as they are to handle great crowds, have had to accommodate, all reached Moscow in comparative comfort and nearly always on time. The comparison between the treatment received at the hands of the railroad officials of neighboring countries, such as Austria and Germany, by whom no reduction in fares was allowed, was distinctly favorable to the Russians. There was not so much huddling of passengers into crowded compartments for night rides, and very seldom were they required to travel in cars of the class below that for which they held tickets.

Any uneasiness as to personal inconvenience at the frontier vanished before the courtly reception of the Russian officials. At once the impression was conveyed that the doctors were the guests of the nation, and that everything possible was to be done to make them appreciate the fact. Nearly every one had come to Russia with the idea that passport and customs inspection at the border would be annoying at least, and all were agreeably disappointed to find that these expectations were not to be realized. As the president said, in his opening address at the first general session, it was the East of

Europe welcoming the West of Europe, but it was always *Europe*, and the greeting was not from stranger to stranger. As one penetrated further into the country, one realized that Russian hospitality is not merely a name. Those who came by way of Odessa found, more than one thousand miles from Moscow, a committee waiting to receive them, which had guides and carriages for them, and entertained them at a supper and concert in the evening. At Kiev a committee made the mysteries of the Russian language easy in the relations with the townspeople, and enabled the stranger guests to see the quaint and curious sights of the Jerusalem of Russia, the oldest holy city of holy Russia. At Warsaw the doctors from the West found other committees equally ready to make their visit a pleasantly memorable one. Meantime, the doctors themselves put up with the inconveniences of traveling in crowds with their usual good nature. The railroad restaurants were utterly unused to such crowds, and the scramble for food at the ordinary eating-places was a struggle for existence in which, in true Darwinian style, the weaker went to the wall. But everything came to him who waited, and Russian forethought had anticipated the difficulty and at other stations extraordinary preparations were made and all wants satisfied. Doctors are doctors the world over, and in a babel of tongues that defied elucidation the burning medical questions of the day were discussed. In the intervals, the foreigner read Tolstoi or the inevitable Bædeker, while some of our Russian confrères were dipping into our literature in order to comprehend us better when we should meet on the floor of the hall of debate. One whom I saw had "The Light that Failed," and another "Trilby." How thoroughly they were able to understand our characters after these literary experiences may well be imagined.

We really only understood all that the committee had done to make us at home when we reached Moscow. At once the Lodging Committee found rooms for us, all a little expensive, to be sure, for Moscow has more visitors than she ever had before, on a peaceful mission, at least. There are more than 10,000 here on account of the Congress, and 7500 of the number are physicians and their female relatives, more than one-half of the former being Russians. Germany and Austro-Hungary have each sent about 800 delegates, France 400, Italy about 400, England 300 (according to Sir William MacCormac), and the United States about 120. The arrangements for accommodating this immense crowd at moments when its members come together are excellent. The Central Bureau is in a huge building 500 feet long and 125 feet wide, built for the indoor maneuvering and inspection of troops. It has kindly been lent by the government. The general sessions are held in the Grand Imperial Theatre, which is probably the largest in Europe and seats more than 4000 people.

Every day about lunch-time most of the visitors meet in *La Manège*, the hall of maneuvers, and crowd it to its capacity, showing how useless would have been the effort to transact the business of the Congress in any ordinary building. Here are the post-office department,

a money-exchange office, the General Committee's office and the bureaus of the various sections, besides a restaurant. Nothing has been forgotten, and as time goes on, the enthusiasm over Russian hospitality waxes rather than wanes. The social features are to be such as the crowd can enjoy in its entirety. There has been a reunion, with supper for all, in the galleries of the Hall of Commerce, and a musical soirée in a public garden and a ball at the Noble's Club, another of Moscow's large buildings, are to be given next Monday.

The first general session was presided over by the Grand Duke Sergius Alexandrovitch, governor-general of Moscow, who has ably seconded the committee in all its efforts to make the Congress a success. The Grand Duchess occupied one of the boxes with the ladies of her suite. The first part of the proceedings consisted in listening to the greetings of the delegates of the various governments to the Congress. The German ambassador, General Rohler, brought the assembly to its feet when, at the end of his greeting, he called down a blessing on the Czar. It is the imperial generosity and liberality which has made the success of the Congress and a becoming exhibition of Russian hospitality possible. Mention of the name of the Czar frequently called forth enthusiastic applause. It was the "Little Father" of all the Russians, not the absolute monarch of the two Russias whom the cultured though heterogeneous assembly united in applauding.

It had already been announced that the trip to St. Petersburg and return would be free, and the representative of the municipal council of the city invited the delegates for the three fête days, the 28th, 29th, and 30th of August. Moscow, he said, is the heart of Russia, but they would find in the North that while the head might deliberate the welcome would be as cordial.

The preliminary business of reception being over, Virchow advanced and received an enthusiastic ovation from the immense audience that showed how much the medical world appreciates the labors of the grand old man of medicine. Instead of speaking, as announced, on "The Rôle of the Vessels in Inflammation," he reserved this theme for his paper before the Section on Pathology and spoke of "The Continuity of Life as the Foundation of Biology and Pathology." It gave him the opportunity to trace the rise of the cellular pathology with which he has had so much to do, and to review the stormy discussions which have divided scientific opinions during the second half of the century. When he reviewed spontaneous generation he paid a glowing tribute to Pasteur, which was the signal for prolonged applause. He complimented the medical world on the fact of having educated public opinion, so that now unfounded theory does not receive so ready acceptance as in the early part of the century. Much remains to be done, but still no minister of public instruction would want to found in our day a professorial chair at the University for Animal Magnetism, as was done during the Forties. Theory is giving place to science at last, and more and more is being attributed to living agencies rather than to dead chemic or other scientific forces. This is the line of true

progress, and he who studies serum as serum for its chemic constituents, and not as the result of the forces which made it, is sure to go wrong. The talk was delightfully discursive, as the reminiscences of the veteran recalling the half century in medicine *quorum ille pars magna fuit*.

Lannelongue reviewed the sclerogenic treatment of tuberculous abscesses, but made the old subject new, in a charming French address, which made one think, when the end was reached, that surely at last the millennium had come in the treatment of cold abscesses. Then Lauder Brunton, on "The Relations between Physiology, Pharmacology, Pathology, and Practical Medicine," vindicated the claims of chemistry to the gratitude of medicine. As time went on this debt became greater rather than smaller, and now the physiologic processes are resolved into chemistry, and pathology has taken to chemic explanations of disease in the study of the toxins. For him, the horizon of medicine is everywhere *chemistry*, and so, on the same day, at a general session of an International Medical Congress, the last of the Nineteenth Century, there are two essentially opposite opinions as to the lines of the development of medicine.

OUR VIENNA LETTER.

[From our Special Correspondent.]

THE GENERAL ASSOCIATION OF AUSTRIAN WOMEN AND THE REGULATION OF PROSTITUTION—BARON ROTHSCHILD'S BLOOD AND THE TENDENCY TO FORM MONEY ROULEAUX—KOCH'S NEW SERUM NOT MEETING WITH APPROVAL OR SUCCESS—THE APE COLONY AT SCHONBRUNN AND THE CONTAGIOUSNESS OF TUBERCULOSIS.

VIENNA, August 22, 1897.

SHORTLY before the close of Parliament a petition was presented to that body on the part of the Allgemeiner Oesterreichischer Frauenverein (the General Association of Austrian Women) asking for the abolition by law of the licensed houses of prostitution in Vienna. The petition was laid on the table by the committee to which it was referred in the ordinary course of parliamentary routine, but not until some remarks had been made which found their way into print, and which were to the general effect that the women should mind their own business. Some remarks on the petition, its signers and its contents were made after the adjournment of Parliament in the *Wiener klinische Wochenschrift*, and these were answered by two prominent members of the Women's Association in the last number of the *Wiener klinische Rundschau*. That this will not be the end of the discussion seems probable, especially as up to the present time the women have the best of the argument, to say nothing of their having had the last word. Meantime, the political press has taken the matter up, too, and so the whole problem of dealing with the social evil is being discussed from various points of view. The attempted solution of it here by the legal licensing of houses of prostitution, and the issuing of "books" (*i. e.*, licenses to ply their trade to prostitutes living apart, the books containing the record of their medical and police inspec-

tions) does not strike one as even a satisfactory makeshift under the circumstances. It makes the formal admission that prostitution is a necessary evil, and thus does away with the best safeguard of the young by the public announcement that continence is considered practically impossible. The favorite argument of the advocates of the legal regulation of prostitution is that the evil has always existed and always will exist, and that as it is inevitably bound up with the conveyance of disease the law has a right to step in for its regulation. Casually, it might be said that there is no form of crime or evil that has not always existed, and that we have not reached the millennium by any means even in our enlightened end of the Nineteenth Century. We have not reached that stage of development, however, in our cult of humanity where we allow the man who has inevitable tendencies toward murder or robbery to put his tendencies into effect provided only he practises his failings on a certain class of the community.

It is often said that the question is not a moral but a medical one; that theology has naught to do with it, and that it is a matter of public hygiene. It is to be hoped that the question of right and wrong in the matter does not cease to have its place because the health of those who voluntarily expose themselves to contagion is threatened.

Under the system here, while the legal acknowledgment of the existence of prostitution, with the moral evils consequent on such a public acknowledgment, is made, the advantages gained are of the most illusory and problematic character. No medical examination, however thorough, can give absolute assurance of the absence of the germs of venereal disease, and only in frankly outspoken cases where the danger of the infection of others is but slight anyhow does it accomplish its purpose. Then the existence of licensed houses and licensed women only seems to leave the door wider open for the existence of what the French call "*prostitution libre*." Quite as much trouble must be taken to suppress this as if legalized prostitution did not exist, and police regulation seems to be as ineffectual in doing it as it does everywhere else. The fact that there is legalization deprives public sentiment of its greatest force. Making a regular legalized business of the matter effectually deters the ordinary young man from taking advantage of what a too-fond paternal government has established, supposedly for his benefit, but does not encourage him to any self-control in the premises, seeing that it is supposed that he is incapable of it. Only the most hardened *roués*, usually well on in middle life, and married men, form the customers at the government's shop. The matter is too broad for discussion even in a letter like this, but those who talk of the regulation of prostitution in the United States by any such measures as here employed should first study closely the practical application of the question as here demonstrated.

Not long ago one of the distinguished clinical professors was summoned to the house of the Austrian member of the famous banking family of Rothschild. He was accompanied by a younger member of the profession who while his chief was making the general clinical examination, proceeded to examine the baron's blood. The

banker was extremely interested in the procedure, and when the examination was concluded asked what he had found. The assistant replied that he had found everything perfectly normal and healthy; that there was the usual number of red blood-corpuscles, showing no marked differences in size or shape, and there was a very normal tendency to the formation of money rouleaux. The distinguished patient, who is well acquainted with the hereditary failing of his family in the matter of successfully forming money rouleaux, but who did not realize that this tendency was so outspoken that it could be discovered on microscopic examination of his blood, was very much amused. He was at first inclined to consider the expression as not quite serious and as meant to stave off questions on the part of an inquisitive patient. When assured, however, that the description was eminently scientific his admiration for the "new medicine" was correspondingly increased. "What is bred in the bone, will out in the blood," I suppose received a striking exemplification for him. When the visit was over and the doctors were leaving the fee the younger man found in the envelope handed him by the baron's secretary was not smaller for his chance excursion all unwitting into the atavistic peculiarities of the Rothschild family in his perfectly commonplace description of the results of a blood examination.

Koch's new tubercular serum has now been in use here for some time, and the results obtained from it seem to be no better than with the original tuberculin. There seems to be no special danger in its use in its present modified form, though it has been noted that patients who, under the ordinary treatment for consumption (plenteous feeding with abundance of light and air), had been gaining in weight sometimes lost in weight after the beginning of the injections. The curative properties of the new remedy, moreover, are very problematic. No one seems as yet to have noticed a frank decrease or disappearance of tubercular patches in the lungs which could be demonstrated by the ordinary physical signs. On the contrary, it has been noted that while patients from systemic accommodation to the remedy could take comparatively large doses of the tuberculin without the occurrence of febrile reaction yet the disease itself could be demonstrated by positive physical signs to be advancing.

Some abscesses have been noted, too, at the points of injection, and the bacteriologic examination of certain samples has shown that it was not always sterile but contaminated at times with staphylococci, sometimes even with streptococci. This seems to be the result of carelessness in filling the receptacles. It is all the more surprising as the preparation is an expensive one, and is put up by a firm to which the work was especially entrusted by its inventor for the express purpose of avoiding such inconveniences. One prominent clinician insists that samples should always be thoroughly examined by culture methods before use.

As in most large cities, Vienna has a never-failing source of amusement for her holiday crowds in the collection of monkeys in her zoologic garden at Schönbrunn. At present there is a gambling crowd of them seemingly in perfect health, but it has not always been so,

and the story of the vicissitudes of the ape colony at Schönbrunn is an interesting chapter in the contagiousness of tuberculosis and the danger of infection from association with the tuberculous. Some years ago so many of the animals became tuberculous and died that their quarters were completely destroyed, everything wooden about them being burned and every possible precaution taken that the new quarters should be absolutely clean. Almost an entirely new collection of apes was purchased, and it was hoped that the trouble was over. Soon the deaths from tuberculosis began once more. Each of the dead animals was kept only long enough to allow of demonstration *post-mortem* that the cause of death was really tubercle, and then the carcass was burned. Notwithstanding this precaution, and frequent careful disinfection, the disease waxed fiercer, and in the course of some months seventy-five of the animals perished from it. The collection was practically annihilated. Careful observation showed that some of the animals had brought the seeds of the disease with them. As apes do not die frequently from tuberculosis in their wild state, it was concluded that the animals became infected while in the hands of the dealers. They are kept by these people huddled together in extremely limited, unclean, badly ventilated and overcrowded quarters while waiting a purchaser. One affected animal would easily infect others, especially on account of the extremely lowered resistant vitality of their utterly unsanitary captivity. The next batch of apes was obtained direct from the Austrian consul in India, and was shipped direct to the zoologic garden. Since then all the specimens from abroad have been obtained in this way and the animals suffer no more from the disease. The system has been in vogue now for about two years and is eminently satisfactory to the management which was beginning to fear that it would be impossible to keep apes at Schönbrunn at all. The lesson learned by this experience is all the more striking as the ape is in general a rather cleanly animal, does not meddle with excretions of any kind and is especially particular about his food, refusing to touch it if it is dirty. In addition, the ape is not a carnivorous animal, so that a number of sources of infection are shut out. The milk which was supplied to them at Schönbrunn was obtained from the cows belonging to the gardens.

A more absolute demonstration of the danger from the contagiousness of tuberculosis could scarcely be had. Intimate association with those affected by the disease, when for the moment the healthy are in poor hygienic condition, or their resistant vitality is lessened, evidently in many cases, is the cause of the disease.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

THE OBSTETRICAL SOCIETY OF PHILADELPHIA—BACTERIA AS A FACTOR IN THE PRODUCE TRADE—PHILADELPHIA'S REPRESENTATIVES AT THE MONTEAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—VITAL STATISTICS FOR THE WEEK ENDING SEPTEMBER 4TH.

PHILADELPHIA, September 4, 1897.

THE first stated meeting since the summer vacation of

the Obstetrical Society of Philadelphia was held on September 1st, and was marked by the presentation of a remarkably able set of papers. The first communication read was one from Dr. Wilmer Krusen, on "The Treatment of Uterine Prolapse," in which a conservative plan of treatment for these cases was recommended, rather than a too-ready recourse to hysterectomy, without due regard to the indications for such a grave procedure. Dr. Krusen summarized the histories of fifteen patients upon whom he had operated, and detailed especially the post-operative course of treatment which he observed. For the operation of perineorrhaphy he considered Emmet's operation undoubtedly the best, and advised its literal application; for anterior colporrhaphy Stoltz's or Hegar's operation is most useful. The discussion which followed this paper was participated in by Drs. Richard C. Norris, John C. Da Costa, and E. E. Montgomery.

Dr. J. M. Fisher read a paper on "Cancer of the Uterus, and the General Practitioner." It was maintained that the general practitioner, because of his neglect of the recognized symptoms of this disease, due perhaps to carelessness in not examining patients with suspicious symptoms, perhaps to his interpretation of such phenomena as belong to the disorders of the climacteric period, oftentimes allowed the disease to progress to a stage at which operative measures are out of the question. Pain, said the speaker, is falsely considered as one of the early symptoms of cancer, whereas in reality it is usually not noticed until late in the disease. It was promulgated as a safe rule that all women presenting at all doubtful symptoms at the time of the menopause should be carefully examined for the existence of carcinoma uteri.

Dr. Richard C. Norris presented a series of "Clinical Notes," dealing with various gynecologic conditions, the chief of which were a case of bilateral broad ligament abscess, and a case treated by means of antistreptococcic serum. Dr. William E. Parke also presented several clinical reports of cases.

While it is true that bacteria have been utilized to some slight extent for the production of a good flavor in dairy products for some time past, it is but recently that the micro-organisms have been grown especially for this purpose, and have become a commercial article in the produce trade, and that thousands of dollars worth of this artificial "starter" in the making of butter and cheese has been sold yearly in all parts of the world.

The headquarters for the dissemination of these bacteria is in this city, where a company has been organized with a capital of \$100,000, and is doing a flourishing business, from all accounts, in this unique line of trade. Already many large dairy companies in all parts of this country, in Canada, in the British Isles, and even as far away as Australia may be found among the patrons of this highly enterprising corporation, and the shipment of culture tubes of the desired germs is reported to be a matter of large interest to the produce trade.

It is claimed that these bacteria produce a uniform flavor in butter, so that the popular "June" flavor may be secured at any time of the year, and that by the same agency the flavor of cheese is regulated to suit the fancy.

of the consumer. It will be interesting to observe how the public and the health authorities take this innovation, which seems to have assumed proportions worthy of attention; for the practice is one which is capable of extensive abuse in the hands of unscrupulous tradesmen, who may care more for the dollar which the "butter culture-tube" brings than for the purity of its contents; so still another commodity is presented for the criticism and examination of the State factory inspectors, who already, in their insufficient numbers, have all they can attend to in other fields.

Philadelphia medical men are well represented at the meeting of the British Medical Association which is about to come to a close at Montreal. A large number of the physicians of this city are in attendance at this convention by invitation, among whom may be mentioned Drs. James C. Wilson, John Ashhurst, Jr., George M. Gould, James Tyson, John H. Musser, M. Howard Fussell, and W. A. N. Dorland.

The deaths in this city during last week numbered 399, an increase of 12 over the preceding week, and of 37 over the corresponding period of last year. Of the total number of deaths, 150 occurred in children under five years of age. The number of infectious diseases did not differ materially from that reported last week.

TRANSACTIONS OF FOREIGN SOCIETIES.

Berlin.

THE ADVANTAGES OF PUNCTURE AND CONTINUOUS DRAINAGE IN DISEASES ATTENDED BY EDEMA—THE CLINICAL DIAGNOSIS OF SCROFULA—ENDOCARDITIS TRAUMATICA—CANCER OF THE ALIMENTARY TRACT, ESPECIALLY WITH REFERENCE TO ITS TRAUMATIC ORIGIN.

BEFORE the Medical Society, May 26th, Ewald spoke of the advantages to be derived from puncture and continuous drainage, *in diseases accompanied by edema*, such as cirrhosis of the liver, nephritis, heart failure, etc. The following case was presented as illustrative of the subject: A man developed an acute attack of nephritis and was admitted to the hospital August 31, 1896, with uremic symptoms and marked edema. Delirium rapidly followed. The urine contained two per cent. of albumin, hyalin casts, and red and white cells, but no pus. The abdomen was tapped and the ascitic fluid removed. In addition, one and sometimes two trocars were kept in each leg. From September 10th to December 3rd forty-five pints of fluid was obtained from the legs in this way. The pleural cavity was tapped five times, and forty ounces of fluid obtained. From October 6, 1896, to March 13, 1897, the ascitic fluid was drawn off forty-five times and measured 291 pints, a quantity weighing considerably more than the patient himself. During this treatment the amount of albumin in the urine varied, but, on the whole, constantly grew less.

The final results of the treatment were satisfactory. Not one of all these punctures was followed by necrosis, gangrene, or erysipelas. Only once there was a slight dermatitis, which occurred without known cause, and rapidly subsided under the use of compresses saturated

with alcohol. The patient, when presented, still had some edema, but all trace of ascites was gone, and he was in fairly good health. There was a little hypertrophy of the heart. At one time, for a short period, the type of the ascites changed from serous to chylous.

Ewald had seen good effects follow this continuous drainage in numerous other cases, and he warmly advocated the practice of allowing the escape of accumulated fluid as soon as possible. The advantages of this removal are so apparent as scarcely to need mention; the pressure upon the vessels of the abdomen, upon the intestines, and upon the liver is at once relieved; and still more important, perhaps, is the relief of pressure upon the heart and lungs. As a natural result, all these organs can better perform their functions, and Ewald was of the opinion that he had saved several patients from death by a timely and thorough tapping and drainage. Of course, no one must make the mistake of supposing that a cure is affected by this treatment. The disease which caused the edema, in this patient remains, but, although he has the nephritis to contend with, he is in a totally different condition to meet it than he would have been without this relief.

Klemperer urged against this treatment the fact that collapse or even fatal hemorrhage may follow it. It is not difficult to understand that the sudden and too great relief of pressure on the abdominal vessels is followed by their great distension, and by a corresponding withdrawal of blood from the brain.

Senator admitted the possibility of hemorrhage from the portal vessels, though he had never seen such an occurrence. To avoid this, all of the ascitic fluid should not be withdrawn at one time, and further, the patient should lie down during the process of tapping.

In closing the discussion, Ewald said that it would indeed be foolhardy to withdraw six or eight liters (quarts) of ascitic fluid during ten minutes; that one ought to use a small trocar so that the fluid passes away very gradually. He himself uses a needle not much more than twice the thickness of a knitting-needle. When the tapping is performed in this manner, the vascular system has time to accommodate itself to the condition of altered pressure, and the extra time thus lost to the physician is time well spent. He had never seen bad results, due either to cerebral congestion or to abdominal congestion or hemorrhage, follow, and he said it was not clear to him that the relief of pressure could result in the rupture of a blood-vessel, as by that very relief of pressure the over-action of the heart would be reduced.

At the session of June 16th, Neumann spoke of the *clinical diagnosis of scrofula*, which he defined as identical with tuberculosis, a "scrofulous diathesis" being simply a tuberculous one, and a "disposition to scrofula" merely a disposition to tuberculosis. The commonest development is in the glands of the neck. It has been suggested that the infection here is from the throat, but this has not yet been proved. Certain it is that tuberculosis of the tonsils in children, when the lung is already affected, can only rarely be demonstrated, and primary tonsillar tuberculosis is not of any more frequent

occurrence. The bronchial glands are often affected. This causes a bronchial breathing over the second, third, and fourth costosternal articulations. If the mediastinal glands are affected there may be cough similar to that of whooping-cough.

From the ninth to the fourteenth year, in addition to the swelling of the glands, scrofula produces chronic inflammatory changes in the ears and nose, and also in the gums and teeth; from the third to the eighth year eczema of the face, and conjunctivitis are also common. In contradistinction to these symptoms, during the first four years of life the manifestations of scrofula are almost exclusively those in which the presence of the tubercle bacillus can be found; scrofuloderma, tuberculosis of the bones and joints, meningitis, and tuberculosis of the lungs and abdominal organs. In thirty-six per cent. of the cases of scrofula the parents of the child have symptoms of tuberculosis.

At the session of the Union for Internal Medicine, held May 31st, Litten read a paper on *endocarditis traumatica*. He excluded from consideration under this title all instances of tearing or bruising of the valves in cases in which endocarditis is already present, as this may occur, even resulting in death, without there being any trauma. Neither does the term include those cases in which an accident causes a fully compensating heart in which a lesion is present to become uncompensating, nor those instances, of which many have been recorded, in which, after an injury, germs enter the blood, and fasten themselves upon a valve. These are cases of septic endocarditis resulting from general infection. There are left cases of simple, benign verrucose endocarditis, which have followed so directly upon the receipt of an injury that they undoubtedly are to be regarded as its direct result. Such a case is the following: A healthy young man was crushed by a horse against the side of a stall. As a result he developed pain, anxiety, palpitation, chilliness, fever, dyspnea, and cyanosis. Some months later signs of mitral insufficiency and endoarteritis developed, which ordinarily lead to aortic stenosis. In only one case of this kind had Litten seen the traumatic endocarditis result in recovery; all the others became chronic.

In the discussion of this paper, on June 21st, Führbringer stated, (1) That all affections of the heart may be rendered much worse as a result of trauma; (2) that even in healthy persons a temporary severe disturbance of function may result (acute dilatation); (3) that injury of the cardiac muscle may be followed by myocarditis; and (4) that valvular incompetence may follow tearing of a valve.

The writer thought it had not been proved that true inflammatory endocarditis could follow traumatism. Stenosis of a valvular orifice might of course result from the cicatrix due to a rent, but this is quite different from stenosis resulting from specific inflammation.

Von Leyden mentioned the case of a boy twelve years of age, who was thrown down and struck upon his breast by a school-teacher. A fever developed and six weeks later the boy died. Suppurative peri- and endocarditis, with calcification were found, the valves being involved.

In such a case it is difficult not to recognize the relation of cause and effect between the accident and the disease.

Litten said that the occurrence of typical endocarditis with papillary excrescences in these cases had been so thoroughly proved by autopsies that its existence can hardly be doubted. The traumatic breaks in the endocardium presumably furnish the means of entrance for the germs which are circulating in the blood, and in them and in the extravasations the germs find a suitable soil for growth.

Boas reviewed from an etiologic point of view *sixty-two cases of cancer of the alimentary tract*, which he had seen. In only three instances was there a history of cancer in the parents of a patient, and only seven times in the person of some other near relative. Heredity, then, possesses but little significance as a point of diagnosis. Quite the reverse is true of trauma. From the records of his polyclinic his assistant had been able to collect thirty-four cases of carcinoma of the alimentary tract possessing a traumatic history. In six of these the cancer was of the stomach. From four years to two months elapsed before the patients complained of symptoms. This fact raises the question as to the length of time which a cancer may exist before symptoms manifest themselves. Boas said that he agreed with those authors who associate a slow growth with a longer latent period. Traumatism under such circumstances may stimulate the sluggish cells of a slow-growing tumor to greater activity. The younger the individual, the more certain the relation between trauma and tumor.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-fifth Annual Meeting, Held at Montreal, August 31 to September 3, 1897.

[Special Report to THE MEDICAL NEWS.]

GENERAL SESSION.

THIRD DAY—SEPTEMBER 2D.

THIS session was devoted to the Address in Surgery by MR. W. MITCHELL BANKS of Liverpool. His subject, "The Surgeon of Old in War," proved one of the most interesting of the entire meeting, both from a historic and heroic standpoint. At its conclusion, Sir William Huntington moved a vote of thanks to Mr. Banks for the pleasure his address had given them, which was seconded by Dr. W. W. Keen of Philadelphia, and carried by acclamation.

The other events of the day were the luncheon upon the "Mountain" in a beautiful open pavilion commanding a superb view of the entire city and the majestic St. Lawrence for nearly thirty miles. This was given to about 250 of the English members and noted guests by the Mayor of Montreal, and was followed by brief speeches by Lord Lister, Lord Mount Royal, Mr. Wheelhouse, Dr. La Marche, and others.

In the later afternoon, the foundation-stone of the Nurses' Home of the Montreal General Hospital was laid by Lord Lister. Short speeches were made by Lords

Aberdeen and Mount Royal, and by the Mayor and Dr. Roddick.

At night was held the most impressive and ponderous social event of the whole meeting—the Annual Dinner. The huge dining-hall was beautifully draped with flags and the crests of the different provinces of the British Empire, and tables were laid for 600 guests. The good old, time-honored toasts of “The Queen,” “The Houses of Parliament,” “The Army and Navy,” were responded to by a long (and appalling) array of speakers, chief among whom were Lords Aberdeen, Lister, and Mount Royal, Professor Michael Foster, Dr. W. W. Keen, Sir Walter Foster, Sir Wm. Van Horn, the Mayor of Montreal, the Mayor of Toronto, etc. The event of the evening was one not down on the program, the presentation of an address to Lord Lister by Dalhousie University, Halifax, N. S. This address, coming literally from the very ends of the earth, and the extraordinary outburst of enthusiasm which it evoked, the whole company, grave and reverend seigneurs as most of them were, leaping to their feet and waving their napkins in the air and cheering “three times three” again and again, completely overcame the grand old man. He wept like a child, and it was some minutes before he could control his voice sufficiently to express his thanks for both honors, which he did in a few simple but exquisitely chosen words.

During the afternoon, an international golf match and tea were given by the Royal Montreal Golf Club, on their beautiful grounds near Lake St. Louis, which were courteously placed at the disposal of members and guests of the Association during their entire stay.

FOURTH DAY—SEPTEMBER 3D.

The paper of the afternoon was the Address in Public Medicine by DR. HERMAN M. BIGGS of New York. (See page 321.) It was heard with great interest, and at its conclusion a vote of thanks to the distinguished author was moved by Dr. Montizambert of Montreal and seconded by Dr. Harvey Littlejohn of Edinburgh.

The President of the Council, Dr. SAUNDBY, then moved that “this meeting recommends his Excellency, the Earl of Aberdeen, K.C.G., C.M.G., and Lord Strathcona and Mount Royal for election as honorary members of the British Medical Association.” This was seconded by the Treasurer, Dr. Parsons, and carried unanimously. The President, Dr. Roddick, moved the endorsement by the Association of the extension of a system of District Nursing throughout the Provinces of the Dominion, which was seconded by Dr. Barnes and carried.

An invitation was presented on behalf of the American Public Health Association by the Chairman, Dr. Benjamin Lee of Philadelphia, to attend its Twenty-fifth anniversary in Philadelphia October 26th, which was received with thanks, and ordered published in the journal of the Association.

The meeting then adjourned with the usual vote of thanks to the President.

The other events of the day were garden-parties, a second excursion down the Lachine Rapids, and a game

of lacrosse between the St. Regis Indians and the Montreal Club in the afternoon.

In the evening a reception was given in the beautifully lighted grounds and buildings of the McGill University by the Faculty, the chief feature of which was the unrolling of a mummy (presented to the museum by Dr. Roddick) by Professor Macalister of Cambridge, who interpreted the inscriptions upon the bandages as they were unwound, in an appallingly edifying manner.

SECTION IN GENERAL MEDICINE.

SECOND DAY—SEPTEMBER 2D.

THE DIETETIC TREATMENT OF DIABETES

was the subject for discussion and was opened by DR. ROBERT SAUNDBY of Birmingham, England. The usual diabetic diet, he said, with its rigid restrictions, can only be carried out by the doctor's authority and the patient's docility. Compromise is the rule, but it is arrived at by the doctor's opinion being sacrificed to the exigencies of the patient. Diabetes mellitus is a clinical group, of which the cases and proper classification are debatable, and on that account variations prevail on views of treatment.

Glycosuria is an abnormal phenomenon, and occurs when the amount of carbohydrates ingested exceeds the utilizing capacity of the body. This capacity varies in different individuals and perhaps in the same person at different times. Those who become easily glycosuric from slight excess stand in close relationship to the milder form of diabetes. In severe cases of diabetes, glycosuria persists even on flesh diet, a fact explained by the formation of carbohydrate molecules when albumen is converted into urea. Hence, in severe diabetes, there is no physiologic reason for persisting with strict diet in the hope of thereby removing the glycosuria.

We must look to clinical results in the hope of justifying our treatment and must not be led too far by our prepossessions in favor of any disputed pathologic doctrine. Instead of following blind routine, we should give each patient as great a quantity of carbohydrates as experience shows can be assimilated. The following daily allowance will be suitable in an average case: Milk, 1½ pints; baked potatoes, 6 ounces; levulose, 1½ ounces, and in mild cases, 4½ ounces of dry toast. Fat bacon may be allowed at one meal, if tolerated, but diabetics absorb fat badly. Alcohol, in the absence of albuminuria, may be allowed in quantities up to 4 ounces, especially if taken with dilute mineral acids. It is of great importance to prescribe definite quantities, and to test the effect of the diet by weekly body weighing, measurement of the urine, and estimation of the sugar, the first of these being the most important.

DR. SIDNEY COUPLAND of London, England, concurred in the view that no hard and fast lines can be drawn in the employment of a restricted diet; indeed, he has often found that the attempt to enforce the use of an exclusive nitrogenous diet has resulted disastrously to the patient, diabetic coma frequently supervening, especially in cases in which there is a tendency to mental deterioration.

DR. R. SHINGLETON SMITH of Bristol, England, thought that while dietetic latitude might be allowed aged

diabetic patients, in the case of the young a more or less rigid exclusion of carbohydrates must be insisted upon.

DR. EBENEZER DUNCAN of Glasgow pointed out that the percentage of sugar in the urine is not the sole criterion of the progress of the disease, nor the elimination of sugar from the urine the only consideration. Cases due to disease of the pancreas are not affected by dietetic treatment, while those of a neurotic type are positively benefited by a restricted and non-saccharine diet.

DR. JAMES TYSON of Philadelphia said that in mild cases the glycosuria is controlled and even cured by dietetic treatment. Glycosuria to the extent of two per cent. must be treated by restricted diet or it will invariably run into diabetes mellitus. For two days during each month, he is in the habit of testing the effect of an exclusively proteid diet in his milder cases, and alternating this test, he has experimented with the effect of carbohydrates, also once a month. The polyuria in diabetes he believes to be the result of the glycosuria. A purely proteid diet increases diacetic acid in the urine, and the possible accumulation of this toxin in the blood must not be lost sight of in pursuing a rigid proteid form of diet.

DR. A. JACOB of New York said that the age of the patient is an all-important factor in the treatment of the disease. Carbohydrates should, as far as possible, be withheld from children, whereas the old may be allowed more latitude of diet, and if emaciating, must of necessity be allowed carbohydrates. He strongly advocated the use of milk, not as an exclusive diet, but as a most beneficial article of diet in diabetics of every age and type. He has not found any benefit to result from the use of skimmed over other forms of milk.

DR. LINDSAY of Belfast, Ireland, has found all treatment futile to save life in case of the young. Life may be prolonged for a few years and the disease palliated but not cured.

DR. SAUNDBY, in closing the discussion, wished it understood that he did not advise latitude in the dietetic treatment of disease only in so far as such latitude is guided by the results of experiment. Individual and not routine treatment should be employed in every case.

DR. EBENEZER DUNCAN of Glasgow then read a paper, entitled

THE TREATMENT OF DIABETES BY URANIUM NITRATE.

He said that Dr. West's paper, read before the Association in 1895, had revived interest in this form of treatment. Dr. Duncan believes that the cause of partial failure in the use of this remedy in diabetes is due largely to the insufficiency of the doses commonly administered. To obtain the best results 12 to 15 grains of the drug must be taken three times a day, preferably after meals. The possibility of exciting gastritis and nephritis, however, must be guarded against. He has found 15-grain doses quite safe. Since April last he has been testing the remedy carefully at the Glasgow Royal Infirmary, and in only one out of six cases—an advanced and hopeless one—had he found it disappointing. These six cases included persons varying in age from early manhood to old age. He has found also that the withdrawal of the drug at too

early a stage has been immediately followed by a return of all the diabetic conditions. With the one exception noted, all the patients under treatment are at the present time free from the presence of any sugar whatever in the urine, and a corresponding improvement in the general health has followed. He believes the cause of the diminution and elimination of sugar from the urine by means of this agent is due to its stimulating effect on the sugar-consuming cells, and not, as West claimed, dependent upon its power of consuming and digesting large quantities of starch.

DR. TYSON said that he had tried the treatment of diabetes with uranium nitrate twenty years ago, but abandoned it. After reading Dr. West's paper recommending larger doses, he resumed its use, and although he did not reach the large doses of from 8 to 10 grains, he could not obtain results from its use that warranted him in continuing it. One untoward effect which he had met with was a persistent diarrhea.

DR. DUNCAN, in replying stated that it will be found upon careful observation that the diarrhea complained of was due not to the uranium salt, but to over-feeding. He did not claim the drug to be a specific, but in his hands it was certainly at present proving a most promising remedial agent in diabetes.

DR. J. E. GRAHAM of Toronto read a paper on, and presented a case of

CROSSED HEMIPLEGIA, THE RESULT OF INJURY TO THE PONS VAROLII.

The accident occurred when the boy was eighteen months of age, and consisted of a penetrating wound of the left side of the soft palate from a splinter. The injury was followed by traumatic convulsions. He is now fifteen years of age, and is still subject to convulsions at varying intervals. There is hemiplegia of the side opposite to the injury, the paralysis being less marked in the lower than in the upper extremity. The face is drawn to the left side. The patellar reflex is exaggerated. Convulsions are general. Intelligence fair, but slightly impaired. Speech is drawling, swallowing of solids difficult. There is general atrophy of all the muscles of the right side, and ankylosis of the right elbow and wrist.

DR. ANGELL of Rochester, N. Y., cited a case of tumor of the pons varolii in which there was no diminution of the reaction of degeneration, indicating that the lesion was about rather than within the pons. He advocated operative treatment in Dr. Graham's case for the relief of the fixed flexion of the elbow and wrist.

THE BACTERIOLOGY OF PERTUSSIS

was the subject of a paper by DR. HENRY KOPLIK of New York. He employed hydrocele fluid as a culture medium in his experiments on account of the impossibility of generating the disease in animals. The small white pellets of mucus coughed up during the early stage of pertussis, he found to contain in their meshes an organism capable of isolation, and in his opinion this is the specific germ of the disease. He succeeded in obtaining excellent cultures in thirteen out of sixteen cases in which the experiment was carried out. The organism is very

similar in appearance to the bacillus of diphtheria, although but half its length. He has not yet completed his investigations of this subject.

DR. J. H. MUSSER of Philadelphia then read a paper, entitled

DISAPPEARANCE OF (PRESUMABLY ORGANIC) CARDIAC MURMURS

in the course of which he stated that mitral regurgitation disappears more rarely than any other murmur. Many so-called organic murmurs are undoubtedly choreaic and functional in character, and hence their disappearance can readily be accounted for. Many organic murmurs vanish on account of ensuing cardiac dilatation. Such dilatation has been found *post-mortem* to so effect the auriculo-ventricular orifice as to render the ventricular cavity continuous with the cavity of the auricle. Some cardiac sounds disappear or are modified in consequence of increasing calcareous deposits upon the margin of the valves. The subject, he said, requires further study and investigation.

DR. JAMES T. WHITTAKER of Cincinnati read a strong plea in justification of the continued use of

TUBERCULIN (KOCH'S) IN THE TREATMENT OF PHTHISIS.

He has used it in the Cincinnati Hospital during six years in more than 1000 cases, and has yet to experience one serious result from its employment. If on no other ground than for the diagnostic value of the reaction which it invariably gives in phthisis its use is warranted. He cited a supposed case of carcinoma under the left sternocleidomastoid muscle which was operated upon, and a *post-mortem* examination revealed that the growth was tubercle. He had obtained, in the majority of cases, beneficial and even curative results from its use. As soon as tolerance of the serum begins to manifest itself, it should be withheld, and resumed when that tolerance is lost. It requires years in some cases to obtain its full remedial results. He had recently discharged a patient as cured who had been under the tuberculin treatment for two years.

DR. TYSON said that he has experienced great difficulty in persuading patients to submit to the long-continued daily hypodermic injections.

DR. GRAHAM cited a case in which Dr. Trudeau obtained the reaction and confirmed the diagnosis of phthisis when all the usual symptoms were absent.

SECTION IN SURGERY.

SECOND DAY—SEPTEMBER 2D.

DR. JAMES BELL of Montreal read a paper upon
THE OPERATIVE TREATMENT OF CANCER OF THE RECTUM.

This is a subject of great promise, but it finds scant mention as yet in surgical text-books. Nevertheless, the removal of any portion of the rectum is now a feasible surgical operation by the sacral route. An early, thorough removal of cancer of the rectum enables one to give as favorable a prognosis as a similar operation in the breast. Glands in the mesocolon are often palpable when no can-

cer of the rectum exists, so the presence of these glands is not necessarily a contra-indication to operation.

In a large majority of cases of high cancer of the rectum, the symptoms are slight or wholly absent, and early diagnosis is therefore difficult. Electric lighting and inspection of the rectum offers the surest means of diagnosis.

Cancer of the rectum has been removed by the abdominal route, and the two cut ends of the bowel approximated with success; but this is possible in very few cases, and the same is true of the vaginal method. The majority of these tumors should be attacked, therefore, by the sacral method. Omitting the technic of the operation, although the reader said he preferred Heinecke's incision, some practical points were discussed.

1. Previous colostomy is desirable, both to complete the diagnosis, to keep feces for some days away from the rectal wound, and to make a permanent outlet for feces if at operation it should be found necessary to leave an open wound.

2. There are three essentials necessary to the operation itself—absolute cleanliness of the wound, freedom from tension of the cut edges of the bowel, and a perfect suture. The fear of stripping off too much of the mesocolon is an exaggerated one; there is little danger of sloughing if tension is avoided.

3. There should be no hurry in closing the colostomy-wound, as it is better to wait some weeks or months even, until the danger of recurrence has somewhat passed.

Statistics are unreliable as showing the exact percentage of cures, but it is safe to predict that further experience in technic, and especially an earlier diagnosis and operation, will give a higher percentage of recoveries than has yet been obtained.

MR. C. B. BALL of Dublin then read a paper, entitled

TRANS-SACRAL RESECTION OF THE RECTUM.

He opposed the idea that sepsis in these cases in many instances is unavoidable. The perineal route should be abandoned for all cases except those rare ones involving the anus alone. Even if successful, the perineal operation leaves the patient in a miserable state of incontinence. The motility of the tumor in the pelvis is the best indication that the growth may be removed with a fair chance of non-recurrence. Even if recurrence is to be looked for, the removal of the growth admits of a more favorable prognosis, both as to the comfort and length of life, than permanent colostomy.

The maintenance of the pelvic diaphragm (levator and sphincter ani muscles) is most important, and can only be preserved by the sacral operation, with injury to the muscles only in the center of the diaphragm, thus avoiding the nerves which supply these muscles. With a pruning-shears, after the sacrum has been exposed, a cut is made to the right and left of the coccyx and lower part of the sacrum, and then one cut is made across it, a triangular portion being removed. This is more simple and far better than the osteoplastic operations. If the preliminary preparation of the patient has been good and the wound sufficiently flushed, drainage may be dispensed with. Sloughing can usually be avoided by taking the greatest

care in handling the gut, and by snipping lateral attachments as far away from the gut as possible. The essayist's record is 17 cases, with 1 death from operation, a case in which the bowel was completely occluded and could not be thoroughly cleansed. Preliminary colostomy is wholly unnecessary.

DR. W. W. KEEN of Philadelphia called attention to the fact that now no part of the alimentary canal is out of the reach of the surgeon, excepting a portion of the esophagus. The mortality of Kraske's operation (in 115 cases, in his own hands) was 34.5 per cent.: during the last few years it has been less than 9.8 per cent. As to recurrence, taking a limit of four years as a safe guarantee, 15.7 per cent. of his patients have passed this limit, while many of the others have a much lengthened and benefited existence. Other surgeons have had as high as 20 per cent. of permanent recoveries. He believes in a preliminary colostomy, performed one, two or, better, three weeks before the resection of the bowel. Kraske advocates this only in the case of patients with obstruction, but it has an object not only to unload the bowel, but to avoid sepsis, especially in those cases in which it is found impossible to unite the cut ends of the bowel. Moreover, an inguinal colostomy wound is vastly preferable to a sacral anus, without sphincteric action.

The speaker said that a preliminary emptying of the bowel during four or five days is insufficient. He had known of mild purgatives and injections being given during a period of seventeen days without producing complete evacuation of the colon. The presence of indican in the urine will show whether fecal matter is still in the bowel.

The object of osteoplastic resection is to restore the integrity of the bone. This is to be accomplished only by the most perfect asepsis, for there is a surgically produced compound fracture of the sacrum. In women, child-bearing is not interfered with, and men can ride bicycles after the removal of the sacrum, and the speaker therefore advocated the removal of a portion of this bone instead of the osteoplastic operation.

DR. JOHN ASHHURST of Philadelphia said that he had not been so enthusiastic over the operative treatment of this serious malady as the previous speaker, but what he has recently seen in Montreal hospitals, as well as heard during the proceedings of the section, have given him a more favorable view. He too, inclines toward preliminary colostomy. By posterior linear rectotomy, as recommended by some French surgeons, great relief can be afforded. This is naturally a mere palliative, but it is a simple procedure in non-operative cases.

DR. BALL, in reply, said that as he brings down and fixes outside the anus the upper cut end of the bowel, the necessity for colostomy is practically done away with. In resection of the bowel and suture of the cut ends, a preliminary colostomy is desirable.

MR. BERNARD ROTH of London presented an analysis of

ONE THOUSAND CONSECUTIVE CASES OF LATERAL CURVATURE OF THE SPINE TREATED BY POSTURE AND EXERCISE EXCLUSIVELY, WITHOUT MECHANICAL SUPPORT.

Almost exactly one-half of these patients suffered from muscular weakness. More than one-half of these (523) had simple curvature—the letter “C” deformity. If osseous deformity coexists, a perfect cure is impossible. In “C” curvature osseous deformity is an exception, while in “S” deformity it exists in most of the cases. Pain is a most common symptom. Flatfoot of a severe type is found in about one-sixth of the cases, and of a moderate degree in nearly one-third, making almost one-half of all the cases in which to treatment of the spine that of flatfoot is to be added.

Nearly every patient had received some previous treatment, either by massage, gymnastics, or spinal apparatus. All apparatus was at once abandoned. The usual duration of treatment was, by daily visits, for from two to three months. The results were as follows: Cured or much improved, 869; improved, 75; failures or partial failures, 56.

A large percentage of the cured patients, more than one-third, were confirmed by observation from six months to ten years later.

MR. R. T. MCKENZIE described

A NEW SCOLIOMETER,

consisting of a stand with vertical upright and movable pairs of calipers which can be clamped upon the hips and shoulders. Then with an ordinary drawing-frame a tracing of the spine and iliac crests, acromion processes, etc., is made, the tracing upon paper being one-fourth natural size. The patient is then made to bend forward, and tracings of the curve of the ribs are similarly made at various levels.

DR. V. P. GIBNEY of New York believes in, and carries out as far as possible in his practice, Roth's methods of treatment of lateral curvature, and therefore during the past ten years has obtained much better results than formerly. If all cases were thus treated before osseous deformity is established, permanent cures might always be obtained. It is difficult to persuade patients to come daily for three months for gymnastic exercises. In America there is far less pain in connection with lateral curvature than in England, although why this should be the case does not appear. A certain number of stupid patients do better if they wear for a time an appliance until they obtain some little practice in gymnastics and the spine becomes less rigid.

DR. SAMUEL KETCH of New York said that he anticipates the time when parents and teachers and general practitioners also will pay attention to curves in children's spines, and will bring the children for treatment during the early stages. The instrument-maker should be a maker of an instrument merely, and should not be allowed to fit the instrument.

DR. B. LEE of Philadelphia considers that the lumbar region is affected before the dorsal region, and that treatment during this early stage is particularly successful.

DR. G. A. PETERS of Toronto spoke of

GUNSHOT WOUNDS OF THE SPINAL CORD,

giving an able array of statistics of injuries of this nature, for the most part received in the Civil War of the United

States. He then described a case of gunshot wound of the ninth dorsal vertebra, with sudden and complete paralysis and anesthesia below the eleventh dorsal nerve. The wound healed without suppuration. The deep reflexes were permanently lost, but the superficial reflexes in great measure returned. The patient died about four months later.

DR. J. N. COUSINS of Southsea, Wales, spoke upon
THE OPERATIVE TREATMENT OF STRICTURE OF THE URETHRA.

He has discarded cutting operations in almost all cases. The instrument he prefers is a catheter with a bulbous point, a solid, flexible distal portion, and a hollow, stiff proximal portion. These are made of various sizes, and in the course of three or four weeks the patient can accommodate the largest size. Many patients must be handled most carefully, but in only one case had the speaker found it necessary to suspend treatment entirely on account of chills and fever. If even a No. 5 instrument will not pass, the penis is distended with oil, and a small, absolutely flexible fine catheter (distal half a bougie) is passed. If it goes into a pocket it is left in, and a second and third, etc., is passed, until one enters the bladder. In very bad cases urethrectomy and perineal drainage is necessary.

SECTION IN OBSTETRICS AND GYNECOLOGY.

SECOND DAY—SEPTEMBER 2D.

DR. FRANKLIN H. MARTIN of Chicago contributed an address, entitled

A FURTHER REPORT ON THE TREATMENT OF FIBROIDS OF THE UTERUS BY VAGINAL LIGATURE OF THE BROAD LIGAMENT.
